found in 28 brains. The middle cerebral artery accounted for 11, the posterior cerebrals for 8; of the remainder the basilar and anterior cerebral were occluded three times, the communicating arteries twice, and the anterior inferior cerebellar once. In the paired intracranial vessels there was no predilection for either side.

"Stenosis Score"

A comparison of the extent of vascular disease in groups of vessels poses certain problems. A score of 0 to 4 may be allotted according to the maximum change noted along the course of a vessel. This uncomplicated system was adopted in the present series for the comparison of the intracranial vessels, as we felt that the difference between the two groups was so pronounced as to require no further examination. There is, however, a serious disadvantage in using this method to compare the larger cervical vessels in that a comparatively normal vessel occluded by embolus will score more than a vessel diffusely involved throughout its length. In order to avoid this emphasis on a localized site of disease the carotid and vertebral arteries in the two groups were compared by using a scoring system which took into account the findings at all sites examined. In each specimen scores from 0 to 4 were recorded at 27 sites distributed over the innominate, subclavian, carotid, and vertebral arteries, as previously described. In the extreme case of occlusion of all major vessels throughout their course a score of 108 (27 x 4) would be allotted. In order to minimize the effect of the difference in age distribution, the infarct and control series were divded into decades.

The stenosis score shown in Table IV is the total score for each decade expressed as a percentage of the maximum possible score for that decade. The results indicate that in the infarct group the stenosis score for the extracranial vessels was twice that observed in the controls. The only exception to this was in the over-90 age group, where only one patient was concerned in the controls. It should be noted that there were only three patients below the age of 60 in the infarct group compared with 22 controls, and therefore direct comparison between the two groups in these decades is not valid. However, 68% of the patients in both groups lie in the 60–80 age range, and the stenosis score for the extracranial vessels of the infarct group was over twice that of the controls. In these two decades the intracranial stenosis score for the infarct group was between three and six times more than that noted in the control group.

TABLE IV.—*Comparison of the "Stenosis Score" (see Text for Definition) in the Major Neck Vessels and the Intracranial Vessels of the Infarct and Control Groups. The Figures in Parentheses are the Number of Patients in Each Decade*

Multiple Involvement of Cervical Vessels

It is now generally appreciated that when one of the four major cervical vessels is affected by atheroma it is highly probable that one or more of the remaining three vessels will show similar changes. In our material we examined this point in relation to severe stenosis (grade 3) and occlusion in both the control and the infarct series and compared the two groups. Table V shows the incidence in both groups, and the results are tabulated on the presence of grade 3 stenosis or occlusion in one, two, three, or four of the major vessels. It will be seen that in 17 of the 57 infarcts grade 3 stenosis or occlusion was found in all four vessels, whereas only 2 of the 88 controls showed grade 3 stenosis in all four vessels. In spite of this marked difference it is worth emphasizing that grade 3 stenosis was noted in one or more of the four vessels in 29 of the 88 controls.

Correlation of Extracranial and Intracranial Vascular Disease

An attempt was made to examine quantitatively the relation between extracranial and intracranial stenosis. For this purpose attention was paid only to the maximum stenosis in a particular vessel, and the intracranial and extracranial vessels were scored from 0 to 4 according to the degree of stenosis.

Product/moment correlation coefficients (r) were calculated as follows: control group (88 cases), $r=0.2246$; infarct group (57 cases), $r=0.139$.

The coefficients are statistically significant in the control group ($P<0.05$) but not in the infarct group (Fisher, 1946).

Discussion

The frequency of multiple involvement by atheroma of the carotid and vertebral arteries and the high incidence of stenosis at the carotid sinus and in the cavernous part of the carotid artery observed in the present study have been noted by previous observers. There are minor differences in the distribution of the arterial lesions as compared with previous work. McGee *et al.* (1962), for example, found that the vertebral artery within the vertebral canal was the commonest site for stenosis in the vertebral circulation, whereas in the present series the vertebral artery ostia showed the highest incidence. Schwartz and Mitchell (1961) found a higher incidence of stenosis at the carotid sinus relative to the cervical part of the carotid artery than we observed. Nevertheless the pattern of vascular disease in the carotid and vertebral arteries is in broad agreement with the findings of previous observers (Hutchinson and Yates, 1957; Martin *et al.*, 1960; Schwartz and Mitchell, 1961; McGee *et al.*, 1962).

In this paper we have not attempted to analyse the mechanism of infarcts as we are preparing a further communication on this subject, but thrombosis or embolic occlusion of neck vessels is clearly of crucial importance. The speed with which occlusion occurs may leave no time for the development of an adequate collateral circulation, and the lesion itself provides a possible source of emboli that may occlude the cerebral vessels.

Fisher (1954), in a clinical and pathological study of carotid artery disease, emphasized the importance of thrombi arising at the carotid bifurcation as a cause of embolic infarction. More recently attention has been focused on episodes of cerebral ischaemia due to platelet emboli arising from the carotid artery. Millikan and Siekert (1955) first suggested that a cerebral embolus may fragment, and pass through the cerebral circulation, causing only transient cerebral ischaemia. Clinical observations on the optic fundi, where small emboli were seen to pass through the retinal circulation without causing permanent retinal damage, supported this suggestion (Fisher, 1959; Russell, 1961; Ashby *et al.*, 1963). The suggestion that these emboli may be a small aggregation of platelets (Denny-Brown, 1960) was confirmed by the pathological study of McBrien *et al.* (1963). It is uncertain how frequently emboli of this type may be responsible for transient ischaemic episodes, but Gunning *et al.* (1964) suggested that these microemboli, composed largely of platelets and leucocytes and arising from an atheromatous internal carotid artery, were a common cause of repeated attacks of monocular blindness and contralateral hemiparesis.

The significance of stenosis alone—uncomplicated by thrombosis—as a cause of cerebral infarction has been increasingly questioned. The high incidence of neck-vessel stenosis in persons with infarct-free brains was pointed out by Schwartz and Mitchell (1961) and is apparent in our material. Hypotensive episodes may produce cerebral infarction (Adams *et al.*, 1966), and it is very probable that vascular stenosis may, on occasion, increase the likelihood of infarction from hypotension. The importance of episodic hypotension associated with cerebral vascular disease in causing transient cerebral ischaemia has been convincingly argued by Denny-Brown (1951) and supported by Williams and Wilson (1962). Millikan (1965), however, questioned the importance of both episodic hypotension and neck-vessel stenoses as a frequent cause of transient cerebral ischaemia. It is relevant that Vost *et al.* (1964) found no evidence that hypotensive episodes contribute in any of the 255 cases of cerebral infarction they examined at necropsy.

The observations of Brice *et al.* (1964) have also discouraged the suggestion that uncomplicated carotid stenosis may determine infarction. They carried out in-vivo experiments on 13 patients and also made observations using an excised carotid artery in a constant-flow perfusion circuit. They found that the lumen had to be reduced to 2 sq. mm. before significant reduction in flow occurred. They concluded that with a residual cross-section of 5 sq. mm. or more a reduction in flow was very unlikely, even when there were stenoses in series. Our results and those of other observers (Martin *et al.*, 1960 ; Schwartz and Mitchell, 1961 ; McGee *et al.*, 1962) all indicate that multiple severe stenoses of the cerebral blood supply may be present in the absence of cerebral infarction. Confirmatory observations were made during life by Faris *et al.* (1963), who studied 43 volunteers who had no clinical or historical evidence of cerebral vascular disease. Arch aortograms were carried out and in half the subjects some form of arterial lesion was shown in the carotid or the vertebral arteries and more than one vessel was affected in 10% of the subjects.

Not only may there be lack of association between extracranial stenosis and cerebral infarction, but there may also be a lack of correlation between the symptomatology and the site of arterial disease. This point was made by Sutton and Davies (1966), who reported their findings in 330 patients who were referred to them with a clinical diagnosis of cerebral vascular insufficiency and who were examined by arch aortography. They found that in patients with symptoms of basilar artery insufficiency radiological abnormalities were found in only 52%, and that lesions were noted as frequently in the carotid as in the vertebral circulation.

In our material the method we adopted for examining the intracranial arteries enabled us to define precisely the degree of stenosis in each of these vessels, and our analysis throws further light on the significance—or lack of significance—of arterial stenosis in relation to infarction. We found that cerebral infarction was most common in the middle cerebral artery territory and a severe degree (grade 3) of stenosis occurred in over 30% of these vessels. However, the posterior cerebral arteries showed grade 3 stenosis in a similar number of cases, whereas the incidence of infarction in the posterior cerebral territory was considerably less than that noted in the middle cerebral territories. The anterior cerebral artery also showed an appreciable incidence of grade 3 stenosis, for, on the right side, it was noted in one in five subjects in the infarct group and yet infarction was observed only three times in this arterial territory.

Cerebral infarction is a dynamic process with several possible contributory causes, and therefore a pathological study of the type reported will do no more than permit a partial appraisal of the pathogenesis. However, we believe that our findings—particularly those in relation to the intracranial vessels—do not support the view that stenosis alone plays a decisive part in the pathogenesis of cerebral infarction. The high incidence of infarction in the middle cerebral territories, together with an appreciable incidence of vascular change in other intracranial vessels, suggests that emboli may have an even more important part to play than has been recognized previously. We intend to examine our material further with this point in mind.

Summary

The necropsy findings in 57 patients with cerebral infarction and 88 controls are compared.

In the 57 brains, 130 separate areas of infarction were found.

The distribution of vascular disease in the cerebral blood supply is described in both the infarct and the control group. Occlusion of the cerebral arteries was confined to the infarct group and the incidence of stenosis in this group is significantly higher than in the controls.

The results suggest that uncomplicated stenosis is not a decisive factor in the development of cerebral infarction.

We wish to acknowledge the encouragement and advice of Professor J. W. Orr and the generous financial support of the Research Subcommittee of the Birmingham Regional Hospital Board throughout this investigation. We are grateful to H.M. Coroners, Mr. F. G. Hails and Mr. J. S. Marshall, for permission to make use of certain material.

Mechanism of Bronchoconstriction Caused by Cigarette Smoking

G. M. STERLING,[*] M.B., B.CHIR., M.R.C.P.

Brit. med. J., 1967, **3**, 275–277

Inhalation of the smoke of a single cigarette causes brief bronchoconstriction in man (Zamel *et al.*, 1963 ; Pelzer and Thomson, 1966), and it has been suggested that this is due to the irritant action of smoke particles on receptors in the tracheobronchial tree. Other possible mechanisms are the pharmacological activity of nicotine or gaseous products of combustion such as oxides of nitrogen, but it has been shown that neither varying the nicotine content of cigarettes nor removal of nitrous oxide from the smoke alters the bronchoconstrictor effect (Nadel and Comroe, 1961). Moreover, Widdicombe *et al.* (1962) have found that chemically inert carbon particles can cause bronchoconstriction in man and cats and that this effect can be blocked by atropine or by cooling the vagi, indicating that it is a reflex reaction mediated through the vagus. By analogy it has been assumed and stated that smoking in man works in the same way, but there is little direct evidence on this point, and the present study has been designed to investigate this assumption further, through observation of the effect of atropine on the bronchial reaction to cigarette smoke.

Methods

Cigarette smoke causes only slight bronchoconstriction, which is not usually detectable by standard spirometry, and a more sensitive method has therefore been used.

Airway resistance and lung volume were measured by means of a constant-volume whole-body plethysmograph of about 450 litres capacity, as described by DuBois *et al.* (1956). After waiting two or three minutes to allow the air in the plethysmograph to warm to a constant temperature, the subject panted shallowly through a heated flowmeter at two breaths a second, and the flow signal was fed into the vertical axis of a cathode-ray oscilloscope, while a simultaneous plethysmograph pressure signal was fed into the horizontal axis to produce a flat vector loop. A shutter attached to the flowmeter and mouthpiece was then closed by a remotely controlled solenoid and the subject continued to make shallow panting movements against this obstruction, which enabled the lung volume at the natural panting level to be measured plethysmographically. This was called the thoracic gas volume (T.G.V.) and was used to correct airway resistance, since the latter normally varies inversely with lung volume (Briscoe and DuBois, 1958). Functional residual capacity (F.R.C.) was measured by instructing the subject to make panting movements after the shutter had been closed at the end of a normal slow expiration. The angles of the vector loops produced by these manœuvres were measured by alignment against a ruled Perspex disc which rotated within a fixed protractor scale in front of the oscilloscope screen. This method was initially checked against simultaneous photographic traces, and, after close agreement had been found, the latter more laborious method was abandoned.

Each test consisted of six or seven consecutive measurements of airway resistance and thoracic gas volume, of which the last five were used in the calculation of mean airway resistance in cm. H_2O/litre/second. From this value 0.45 cm. H_2O/l./sec. was subtracted for the resistance of the flowmeter and mouthpiece, and the result was then converted to its reciprocal, airway conductance (C.A.), which has a more linear relation with lung volume. Results were expressed as the ratio of airway conductance to thoracic gas volume (C.A./T.G.V.) to allow for changes in lung volume when comparing changes in airway resistance (Nadel and Comroe, 1961).

Subjects

Eleven normal adults, of whom three were non-smokers, were each tested on two occasions. On the first, C.A./T.G.V. was measured at rest and again two to three minutes after 15 inhalations over five minutes of a filter-tipped cigarette. On the second, C.A./T.G.V. was measured at rest, then 25 minutes after the subcutaneous injection of 1.2 mg. of atropine sulphate, and finally after inhalation of a cigarette as before. The two studies were carried out at the same time of day, within a few days of one another, and care was taken to ensure that none of the subjects had smoked within two hours of the experiment, since the bronchoconstrictor effect of a cigarette may last up to 80 minutes (Nadel and Comroe, 1961).

Results

Lung Volumes

Lung volume was measured at both F.R.C. and natural panting volume (T.G.V.), and the results, with the one female subject excluded, are shown in Table I. It can be seen that T.G.V. is generally larger than F.R.C., as has been found previously (Nadel and Comroe, 1961), and this fact is illustrated by the specimen spirometer tracing (Fig. 1). This shows three normal

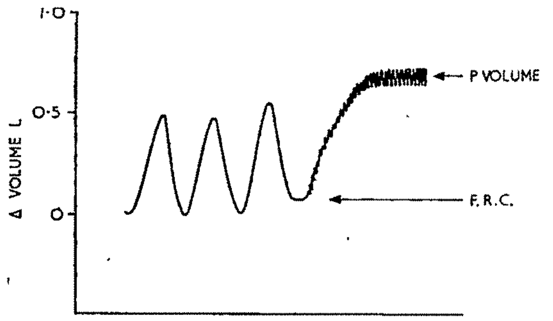

FIG. 1.—Lung volume change with onset of rapid shallow panting after three normal tidal breaths. (P.volume ≡ T.G.V.)

---

[*] Research Registrar, Respiratory Department, St. George's Hospital, London S.W.1.

breaths of 500 ml. tidal volume followed by a period of rapid shallow panting similar to that performed during measurements in the plethysmograph. At the start of panting there is a rapid increase in lung volume for a few breaths, after which lung volume stabilizes for a time though further fluctuations may occur if panting is prolonged. Though this point has been noted before, it has not been emphasized, and in the past there has sometimes been doubt about whether F.R.C. or T.G.V. has been used in the correction of airway conductance for lung volume.

The mean values of 3.98 and 4.61 litres for F.R.C. and T.G.V. respectively are a little high, but this probably represents the selection of fit young men as subjects, and the figures fall within the range of other series (Table II).

Airway Resistance

The mean C.A./T.G.V. of the 11 subjects was 0.205 ± 0.033 [S.D.] at rest before smoking, and 0.21 ± 0.035 at rest before atropine and smoking, showing that there was no overall difference in "bronchial tone" on the two occasions. These values agree well with those of 0.22 and 0.23 obtained from normal resting subjects in previous series (Nadel and Comroe, 1961; Pelzer and Thomson, 1966). However, there was some day-to-day variation within individuals, and anyone who showed a change in C.A./T.G.V. of more than 25% at rest was excluded from the trial.

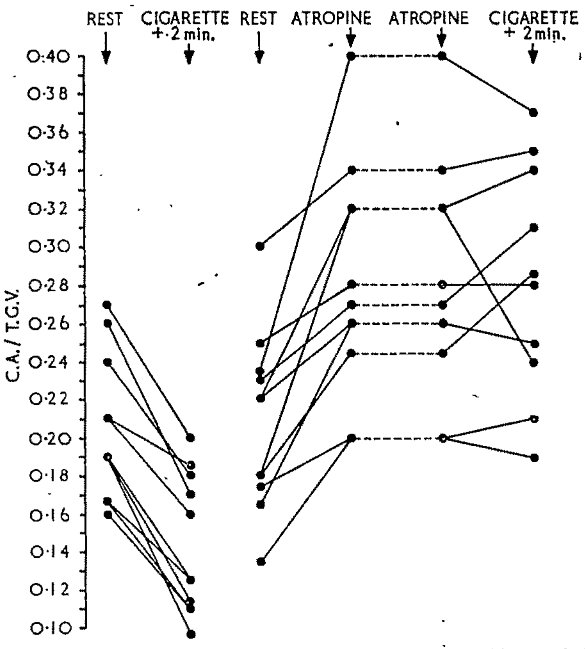

FIG. 2.—Change in C.A./T.G.V. after smoking (left-hand column) and after atropine followed by smoking (right-hand column).

In all the subjects there was a fall in C.A./T.G.V. two minutes after finishing a cigarette, to a mean of 0.14 ± 0.028, which is a highly significant change ($P<0.005$ by Student's *t* test). There was considerable individual variation in this response, with a range of −12% to −53%, but the average change of −31% is very close to that found in an earlier study (Nadel and Comroe, 1961) (Fig. 2). The bronchoconstriction diminished rapidly, and in those subjects in whom it was followed serially C.A./T.G.V. had returned to resting values in 20 to 30 minutes.

After the injection of atropine there was a consistent rise in C.A./T.G.V., from a mean of 0.21 ± 0.035 to one of 0.28 ± 0.63, an average increase of 38%, which confirmed previous findings of resting bronchial tone (Widdicombe *et al.*, 1962). Inhalation of a cigarette after atropine failed to cause any consistent change in C.A./T.G.V., which showed only an insignificant mean fall of 0.6%.

Discussion

These results confirm that the inhalation of cigarette smoke causes an increase in airway resistance, which is maximal within two or three minutes of smoking and usually declines to its resting value over about 20 minutes. It has been shown that this effect is unaltered by extraction of volatile substances from the smoke (Nadel and Comroe, 1961) or by varying the nicotine content of the cigarette smoked, and it has therefore been suggested that the tiny particles that constitute smoke are irritant to receptors in the airways. A similar response has been described in men and cats given chemically inert carbon particles to inhale, and the mechanism has been shown to be a vagal reflex, since in animals it can be blocked both by atropine and by vagal cooling, and since increased activity can be demonstrated in afferent vagal fibres (Widdicombe *et al.*, 1962). Vagal reflexes are also the pathways for production of bronchoconstriction due to mechanical irritation of the larynx (Nadel and Widdicombe, 1962), or to inhalation of low concentrations of sulphur dioxide (Nadel *et al.*, 1965). The prevention of bronchoconstriction by atropine in the present study therefore suggests that the same mechanism is involved, though the afferent side of the reflex arc has not been investigated.

It has generally been assumed that any increase in airway resistance is due to narrowing of the bronchi and bronchioles, but another possible explanation is that irritant particles might alter overall airway resistance by causing laryngeal obstruction through mucosal swelling or muscular contraction, particularly as extrathoracic resistance may comprise as much as 50% of total airway resistance during mouth breathing in normal subjects (Hyatt and Wilcox, 1961). However, it is difficult to see how atropine could prevent such a change except, possibly, by its drying action on the epithelium of the vocal cords. Moreover, in animal experiments, carbon particles inhaled through a tracheostomy, thus by-passing the larynx, still cause constriction of the lower airways, indicating that the latter are the site of at least part of the increased airway resistance.

The fall in resting airway resistance after atropine seen in normal subjects has been described before, and, like the prevention of a provoked rise in airway resistance, is generally attributed to blockade of vagal bronchomotor activity. This is certainly the most obvious and likely explanation, but there is some doubt on whether it is the only one, since the action of atropine in drying up bronchial secretions might be expected to cause some increase in the calibre of the airways. Differentiation of these mechanisms is difficult, but isoprenaline causes a comparable fall in airway resistance without affecting secretions significantly, which suggests that muscular relaxation could account for the major part of the dilator action of atropine.

Summary

Inhalation of cigarette smoke causes bronchoconstriction in both smokers and non-smokers.

This effect is almost certainly due to the irritant action of smoke particles.

It can be blocked by atropine, suggesting that it is brought about by the vagus, probably through the action of the latter on bronchial smooth muscle.

I would like to thank Dr. J. C. Batten for his advice and encouragement, and Miss F. A. Boother for her frequent technical help.

This study was supported by a research grant from the Board of Governors, St. George's Hospital, London S.W.1.

Is the Woulfe Bottle an Efficient Humidifier for Oxygen?

BERNARD J. FREEDMAN,* M.B., B.S., M.R.C.P.

Brit. med. J., 1967, 3, 277–279

Oxygen from cylinders is dry. The need for adequate humidity of inhaled gases in oxygen therapy is generally recognized. There is, however, no unanimity regarding the desirable level of humidity, nor regarding the best means of achieving it. Bubbling oxygen through water in a Woulfe bottle has been the most widely used method of humidifying oxygen since the early days of oxygen therapy. This method has been the object of adverse criticism. It has been alleged that it "does not result in adequate humidification" and that "this method should be abandoned" (*Brit. med. J.*, 1964). Cadman (1961) was of similar opinion. The Woulfe bottle is a widely used apparatus for this purpose, and in many hospitals it is the only one. Before urging the widespread abandonment of a cheap, simple, and easily replaceable apparatus in favour of something complex and expensive, or of giving it up altogether, it seemed desirable to test the efficiency of the Woulfe bottle as a humidifier, since no record could be found of this having been previously done.

There are three questions to answer. What level of humidification does this method achieve within the range of working conditions likely to be encountered? What level of humidification is desirable? Does this method meet clinical requirements? Experiments are described which give an answer to the first question, and an attempt is made to answer the second and third in the discussion which follows.

Material and Methods

Conventional bedside apparatus was used. Oxygen from a cylinder was bubbled through water in a Woulfe bottle and conveyed thence by 1.5 m. (4 ft. 9 in.) of rubber tubing to a hair hygrometer which occupied the position of a face-mask. Oxygen flow-rates were measured with a bobbin flow-meter calibrated against a Parkinson-Cowan gas-meter. The Woulfe bottle measured 14 cm. high and 5.8 cm. internal diameter, and it was filled to a depth of 4.5 cm. (about 160 ml.) with tap-water, the inlet tube reaching to 0.5 cm. above the floor of the bottle. The tube conveying oxygen from the bottle was connected to an opening in one end of a transparent polyvinyl chloride bag. The hygrometer lay within the bag. It fitted fairly snugly so as to ensure adequate entry of humidified oxygen into its casing (Fig. 1). Oxygen left the bag through tubes inserted into the two distal corners. This prevented retrograde entry of ambient air. The hair hygrometer was calibrated against a wet-and-dry bulb whirling hygrometer.

Dry oxygen was passed through water in the Woulfe bottle at a constant rate. At intervals of two minutes or less the following were measured: (1) relative humidity in the bag, and (2) temperature of the water, of the gas in the bag reaching the hygrometer, and of the ambient air. Gas flow continued until stable readings were obtained. Duplicate experiments were performed at flow-rates of 3, 5, and 8 litres per minute in cool, temperate, and hot environments. The hot environment was in the hospital basement alongside the steam-pipes, the temperate was in the laboratory, and the cool was on a ward balcony. Day-to-day variations in weather conditions and in boiler temperatures rendered it impossible to achieve identical ambient temperatures in the experiments carried out within each of the three temperature ranges. Ambient temperatures were as follows:

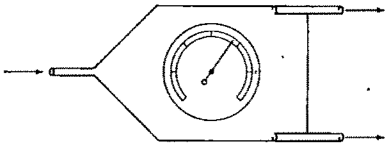

FIG. 1.—Humidified oxygen is passed through the plastic bag containing the hygrometer.

Cool ...	... 11.0–13.4° C.	(51.8–56.1° F.)
Temperate	... 18.5–19.8° C.	(65.3–67.6° F.)
Hot ...	... 27.6–31.6° C.	(81.7–88.9° F.)

Results

After the oxygen was turned on, the humidity rose rapidly. Progressive cooling of the water then led to a corresponding fall in humidity. Eventually the water temperature and the relative humidity were steady. A high flow-rate and a high ambient temperature were associated with much cooling of the water (Table I), and a big drop in final humidity. For example, at 8 l./min. and 31.5° C. (88.7° F.), the water temperature fell as much as 11.6° C. (20° F.).

TABLE I.—*Depression of Temperature of Water in Woulfe's Bottle Below Ambient Temperature*

Ambient Temperature	Oxygen Flow-rate (l./min.)		
	3	5	8
Cool	2·6° C.	3·3° C.	4·7° C.
Temperate ..	3·3° C.	4·2° C.	5·5° C.
Hot	4·7° C.	8·7° C.	11·6° C.

---

* Dulwich Hospital, King's College Hospital Group, London.

Despite the cooling of oxygen that must have occurred, it was always rewarmed to within a degree of ambient temperature in the course of its passage along the tube to the hygrometer. The results shown in Table II are the levels of humidity which were eventually reached after the initial rise and fall when conditions were stable, and are the means of closely agreeing duplicates.

Table II.—*Humidity of Oxygen After Bubbling Through Water in a Woulfe Bottle at Three Flow-rates and Three Ambient Temperatures*

		Oxygen Flow-rate (litres/min.)		
		3	5	8
A. Water-vapour concentration (grammes water per cubic metre oxygen)	Cool ..	8·34	8·75	7·95
	Temperate	13·40	13·03	11·50
	Hot ..	22·74	22·57	19·42
B. Relative humidity (%)	Cool ..	70	70·5	75
	Temperate	79	80	70
	Hot	81·5	68	60
C. Evaporation rate (mg. water evaporated per minute)	Cool	25·0	43·7	63·6
	Temperate	40·2	65·2	92·0
	Hot	68·2	112·8	155·4

Water-vapour concentrations achieved in these experiments (Table II A) ranged from 7.95 g./cu. m. (at low ambient temperature and high flow-rate) to 22.74 g./cu. m. (at high ambient and low flow-rate). A rise in temperature yielded a striking increase in water-vapour content. A rise in flow-rate made little difference. The figures were obtained by calculation from the relative humidity (Table II B), the temperature, and values for water-vapour concentrations in saturated air at various temperatures (Hygrometric Table, 1940).

Table II B shows relative humidities, measured as described in the experiments, which ranged from 60 to 81.5%.

Table II C shows weight of water vaporized per minute, which ranged from 25 to 155 mg., the quantity varying as temperature and flow-rate. The figures were obtained by calculation from concentrations (Table II A) and flow-rates.

The effectiveness of humidification must be judged by the water-vapour *concentration* (expressed here in g./cu. m.) and not by relative humidity or the amount of water vaporized in one minute. Table II A therefore shows the essential results in this connexion. It cannot be too strongly emphasized that relative humidity readings are of limited value and must lead to fallacious conclusions unless taken in conjunction with temperature and expressed as water-vapour concentration. Air or oxygen which is saturated with water vapour at body temperature contains 44 g. of water per cubic metre. The drying power of inspired gases is proportional to the amount by which their water content falls short of this amount. Fig. 2 shows the water-vapour concentration at various relative humidities and temperatures, and has been drawn from values calculated from the Hygrometric Table (1940). Comparison of Table II A and II B shows some of the differences between water-vapour concentration and relative humidity in identical circumstances, and demonstrates the fallacy of accepting the latter in preference to the former. For example, at a flow-rate of 8 l./min. the relative humidity is 75% in a cool environment and 60% in a hot one (Table II B), yet the corresponding water-vapour concentrations are 7.95 and 19.42 g./cu. m. respectively (Table II A). The hot environment thus yields a higher water-vapour concentration, despite the lower relative humidity, than the cool one. Fig. 3 shows water-vapour concentrations occurring during the course of the experiments, strikingly showing the effect of ambient temperature.

Discussion

What level of humidification is desirable? In extreme atmospheric conditions, as in Himalayan mountaineering, there is evidence that during a stay of several weeks under conditions involving strenuous physical activity there is some liability to bronchitis (Pugh and Ward, 1953; Ward, 1953). In these circumstances the cold air at low pressure has an exceedingly low water-vapour content. However, in the range of atmospheric conditions likely to be encountered in clinical practice, air inhaled through the nose is warmed to within a degree or two of body temperature and saturated with water vapour. Perwitzschky (1927) showed that air at 25° C. (77° F.) and relative humidity 24% inhaled through the nose acquires a relative humidity of 99% at 35–36° C. (95–97° F.) by the time it reaches the trachea. Even with mouth-breathing it acquires

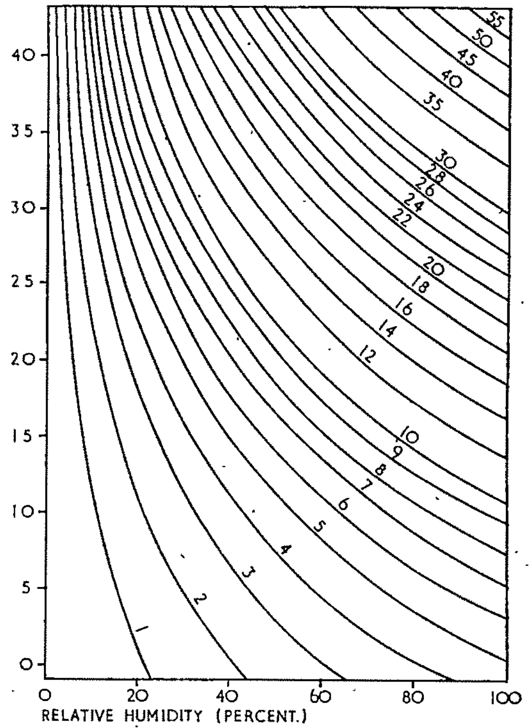

Fig. 2.—Given relative humidity and temperature, the absolute humidity, or water-vapour concentration in grammes per cubic metre of gas, can be derived from these curves. Each curve represents the number of grammes per cubic metre.

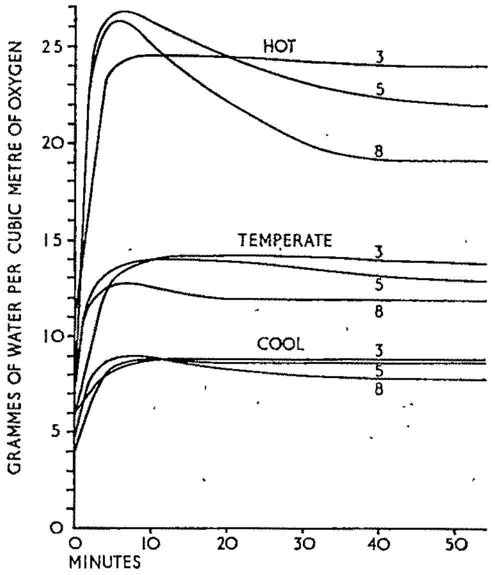

Fig. 3.—Examples of the sequence of changes that occur in absolute humidity (grammes of water per cubic metre) in oxygen when it is bubbled through water in a Woulfe bottle at three flow-rates (3, 5, and 8 litres per minute) and at three ambient temperatures.

a relative humidity of 93% at a temperature of 34.5° C. (94° F.). At the ambient temperature and relative humidity of his experiment air contains 5.52 g. of water vapour per cubic metre.

In the experiments described here the water-vapour content of the humidified oxygen was in the range of 7.95 to 22.74 g./cu. m. This is above the amount which Perwitzschky has shown will rise to almost saturation level at body temperature in the trachea. His experiments were carried out on healthy subjects and lasted five minutes each. It is possible that prolonged mouth-breathing would have led eventually to a lower relative humidity in the trachea.

There seem to have been no comparable experiments in patients. One is therefore obliged to consider the varying circumstances that affect patients, and to speculate on their influence on humidity in the airways and the state of the bronchi. The purpose of humidification of oxygen for inhalation is the reduction of its capacity to dry the mucosa of the airways and of the mucus lying thereon. What constitutes a desirable level of humidification depends on factors that vary from patient to patient. A high level of humidity is required in the following circumstances: sticky mucus, a weak cough, a partially obstructed nose, prolonged mouth-breathing, a tracheostomy, and the use of masks involving admixture with ambient air when the latter is excessively dry.

My experience of many cases of acute chest infection over a number of years suggests that cases of moderate severity receive adequate humidification by the Woulfe bottle method. The indications of inadequate humidification are a dry mouth, strings of sticky mucus in the fauces, a rattly but unproductive cough with an adequately expulsive blast, or the expectoration of small amounts of very tenacious mucus with undue effort. These signs are especially likely to occur in gravely ill patients whose infections are complicated by emphysema or asthma, and in whom the maximal expiratory flow-rate and expulsive blast are much reduced. Patients with acute chest infections who have undergone tracheostomy are in similar plight. These patients require inspired gases which are saturated at body temperature.

Summary

The method of humidifying oxygen by bubbling it through water in a Woulfe bottle has been criticized. This method was tested by bubbling oxygen at three flow-rates (3, 5, and 8 l./min.) and at three ambient temperatures (approximately 12°, 20°, and 32° C.). The relative humidities ranged from 60 to 82%, and water-vapour concentrations from 7.95 to 22.74 g./cu. m. During the first few minutes of bubbling, before appreciable cooling had occurred in the water in the Woulfe bottle, the humidities were still higher. It is thought that humidification of oxygen by this method is adequate for the treatment of most chest infections and for non-respiratory disorders requiring oxygen.

Attention is again drawn to the fallacy of accepting relative humidity alone as a measure of the humidification of gases for inhalation. The need to use measurements of water-vapour concentrations for this purpose is emphasized.

A family of curves has been drawn to facilitate calculation of water-vapour concentration when the relative humidity and temperature are known.

I wish to thank Mr. C. Hinkel, of the Meteorological Office, for advice, and the South-east Metropolitan Regional Hospital Board and King's College Hospital for the grant of equipment and technical assistance.

Heparin as an Analgesic in Myocardial Infarction: A Double-blind Trial

C. J. BULPITT,* M.B., M.R.C.P.

Brit. med. J., 1967, **3**, 279–281

Nichol *et al.* (1959) reported that heparin usually relieves anginal pain, but no controls were employed. This impression has been repeated (*British Medical Journal*, 1966) but never proved. Heparin does not increase forearm blood flow (Lambert, 1958) and there is no evidence of a vasodilator effect. It was decided, therefore, to perform a double-blind study on the effects of intravenous heparin on myocardial pain, blood pressure, pulse rate, and electrocardiographic tracings. Twenty-eight patients with "myocardial infarction" took part in the trial.

Method

The patients had been admitted to a general medical ward, usually in the Medway Hospital. To enter the trial a patient had to satisfy the following criteria: he should have cardiac ischaemic pain but not show more than slight distress; he should not have received an anticoagulant within the preceding few days, nor an opiate or drug of similar analgesic potency within the preceding six hours.

When the patient was first seen by a doctor a quick assessment was made. If the patient was not unduly distressed, and it was thought that no analgesic therapy would be required for 30 minutes, he was requested to enter the trial. He was told that he would receive an intravenous injection of a well-known drug, to discover whether or not it would relieve his pain. One patient who showed distress during this trial was given morphine and withdrawn.

Each patient verbally answered the first of three questionaries. An intravenous injection of either 2 ml. of normal saline or 2 ml. of a solution containing 10,000 units of heparin was then given. The solutions, which were identical in appearance, were prepared in numbered phials and used in numerical order. The code was held by the pharmacist, who had randomly allocated the solutions.

The blood pressure and pulse rate were recorded, and nine patients had an electrocardiogram taken before and after the

trial. After 10 and 30 minutes an identical questionary was answered and the blood pressure and pulse were again recorded.

The questionaries were devised to calculate the degree of pain present and thereby to assess any improvement. A points system provided a numerical basis. Severe pain rated six points, moderate pain four points, mild pain two points, and a "disappeared" pain counted nil. "Improving" counted minus two points, "worsening" plus two points, and "the same" counted nil. A radiating pain is probably more severe than one confined to the anterior chest wall, and plus one point was given for every site of radiation.

Results

Tables I and II show the patients' initial pain score and subsequent improvement or deterioration. The improvement is calculated from the difference between two pain ratings, a positive sign indicating a fall in pain rating and therefore improvement. Also shown are changes in pulse rate and diastolic blood pressure.

The 28 patients investigated had the characteristic pain plus typical electrocardiographic changes (Table I). Twenty-three of them had significantly raised transaminase levels. The patients were divided into two groups. The first group received heparin and the second saline. The heparin group included 12 men and three women, with an average age of 55 years. Two patients subsequently died during that hospital admission. The saline group included 12 men and one woman, with an average age of 58 years; three subsequently died. The only disparity between the groups is that the saline group showed higher transaminase levels. The mean aspartate aminotransferase level of the heparin group was 72 units and that of the saline group 103 units. The mean lactic dehydrogenase of the heparin group was 740 units and of the saline group 1,030 units.

Both groups showed pain relief 10 minutes after the injection. The difference between the two means is not significant (P>0.5). There was no further reduction in pain between 10 and 30 minutes in either group. The analgesic effect of intravenous heparin in myocardial infarction was no greater than that of normal saline.

The changes in pulse rate are of interest. At 10 minutes there was a reduction in rate in the saline group. As indicated in Table I, one patient (Case 35) had atrial fibrillation. The reduction in radial pulse rate was possibly due to the fall in diastolic blood pressure of 20 mm. Hg, the vertex rate not necessarily being altered to such an extent. This finding was included in calculations, and the results are still not significant. (P>0.1).

Between 10 and 30 minutes there was a reduction in pulse rate only in the heparin group. This remains unexplained and is probably not significant (P>0.05). The changes in diastolic blood pressure were minimal in both groups.

The six patients with "coronary insufficiency" had the characteristic prolonged pain at rest without typical electrocardiographic changes or marked elevation of the transaminase levels. The results in this section follow the pattern found in myocardial infarction (Table II). There is a similar degree of pain relief at 10 minutes and minimal improvement thereafter. Again heparin shows no advantage over saline in these patients.

Nine patients had an electrocardiographic tracing taken before the injection and after 30 minutes. Six had received heparin and three saline. Six patients showed no change in their electrocardiographic tracings. A minor increase in ischaemic change was observed in one patient receiving saline and in one receiving heparin. One patient receiving heparin showed a minor improvement in his tracing: an ST elevation of 1 mm. in lead II reverted to the isoelectric line at 30 minutes.

Conclusions

Under the conditions of this trial heparin did not exert an analgesic effect in myocardial infarction greater than that of a placebo, nor did it affect the pulse rate or diastolic blood pressure. There was no significant alteration in the electrocardiographic tracings of six patients who received heparin.

Summary

A double-blind trial was performed to determine the effect of intravenous heparin on myocardial pain, pulse rate, diastolic blood pressure, and the electrocardiographic tracing.

No significant differences were found from the placebo effects of intravenous saline.

I am indebted to Drs. F. A. Richards, R. A. Moir, J. D. Craig, and M. Sadiq for encouragement, criticism, and permission to study patients under their care. The chief pharmacist, Mr. H. Duckett, kindly prepared the drugs and held the code. My thanks are also due to the resident medical staff for their assistance and to Miss D. Rose for secretarial work.

Calcium Infusion Test in Osteomalacia: an Appraisal

J. V. LEVER,* M.B., B.SC.; C. R. PATERSON,* M.A., B.M., B.SC.; D. B. MORGAN,† M.B.

Brit. med. J., 1967, 3, 281-282

Nordin and Fraser (1956), as well as many other authors, have reported that patients with osteomalacia retain more of an infused dose of calcium than normal persons. A high retention of infused calcium by itself has been taken as diagnostic of osteomalacia (Harvald *et al.*, 1962; Deller *et al.*, 1963; Thompson *et al.*, 1966). Nordin and Fraser suggested that the calcium retained in osteomalacia was taken up by the uncalcified bone matrix—that is, osteoid tissue. If this was so then the amount of calcium retained should be related to the amount of osteoid.

We report here the relation between calcium retention and the amount of osteoid in trabecular bone in 15 patients.

Patients

Eleven patients had had a partial gastrectomy, but only four had typical osteomalacia with bone pains and a large increase in serum alkaline phosphatase which responded to vitamin D (Morgan *et al.*, 1965). The other seven were investigated because at that time we thought that a small increase in serum alkaline phosphatase, which they were shown to have, meant that they had a symptomless osteomalacia. Four further patients had typical osteomalacia which was not the result of gastric surgery. Three of these had proved gluten-induced enteropathy; the fourth is still being investigated.

Methods

The protocol for the infusion of calcium was that given by Nordin and Fraser (1956) except that calcium gluconate was infused in a 5% solution of dextrose and not in saline. Calcium in the urine was estimated by flame photometry (MacIntyre, 1961).

The proportion of the dose excreted was calculated from the difference between the calcium excreted in the urine in the 12 hours from the beginning of the infusion and the calcium excreted during the corresponding period on the previous day. The results were expressed as the percentage of the infused calcium retained in the body in the 12 hours.

The bone biopsy specimens were obtained from the iliac crest under local anaesthesia (Williams and Nicholson, 1963). The specimens were fixed in barbitone-buffered formalin (Ball, 1957) and sections cut without decalcification by Russell's (1956) technique. The area of osteoid in the section was expressed as a percentage of the total area of bone in the section. These measurements were made by Dr. C. G. Woods and will be reported by him elsewhere.

Results and Discussion

Fig. 1 shows that while all eight patients with typical osteomalacia retained most of the infused calcium so did four of the seven patients without an excess of osteoid in the bone. There was no relation between the amount of calcium retained and the area of osteoid.

Thus an excessive retention of calcium does not depend on an excess of osteoid. A similar conclusion could be drawn from the data of Thompson *et al.* (1966) and of Deller *et al.* (1963). The results in these two series have been plotted in Fig. 2, which includes our results for comparison. The histological criteria for the diagnosis of osteomalacia have been those of the respective authors.

The high retention of calcium in patients without osteoid is not limited to patients who have had a gastrectomy. Lindahl (1959) reported that a third of 70 patients with senile osteoporosis retained excessive amounts of infused calcium, though none of them had histological evidence of osteomalacia. Atkinson *et al.* (1956) reported an increased calcium retention in 7 out of 14 patients with chronic jaundice. Three of these seven had no osteoid on bone biopsy.

Apart from osteomalacia, high retention of calcium has been reported in other disorders of bone where osteoid is found. Thompson *et al.* reported, and we have confirmed, that in Paget's disease of bone there is an increased calcium retention after calcium infusion. Nordin and Fraser (1956) showed this in hypoparathyroidism, and also in a number of other diseases such as diabetes, rheumatoid arthritis, and renal failure.

The interpretation of calcium infusion tests may be questioned because normal persons retain as much as 73% of an infused dose, yet the retention of a further 10% is regarded as highly abnormal. The fate of the retained calcium is not

---

* Research Assistant, Clinical Investigation Unit, University of Leeds.
† Lecturer, Clinical Investigation Unit, University of Leeds.

known even in normal people. The extra calcium may be accommodated by the growth of immature crystals in bone; or the calcium may be deposited in the soft tissues of the body and not the bone. It would be interesting to know the effect of age on the retention of calcium; it is reasonable to postulate that the calcified soft tissues found in elderly persons have an increased affinity for calcium (Bürger, 1960) and, in addition, many of them have some impairment of renal function. But we do not think such an investigation is justified, and we report these results in the hope of sparing many patients an unnecessary infusion of calcium.

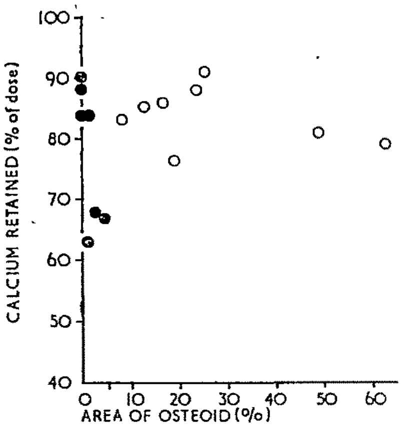

FIG. 1

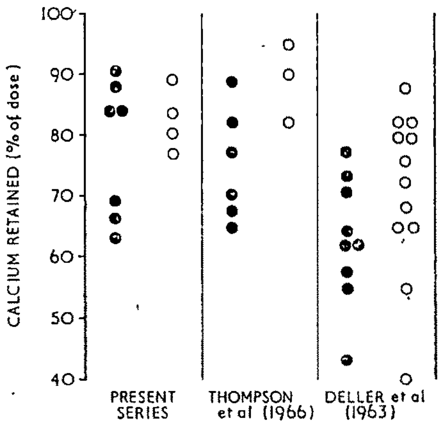

FIG. 2

FIG. 1.—Relation between retention of infused calcium and amount of osteoid (by area) in the bone biopsy specimen in eight patients with osteomalacia (open circles) and seven patients with a partial gastrectomy but without osteomalacia (closed circles). FIG. 2.—Retention of infused calcium in patients after gastrectomy. The open circles represent patients with osteomalacia and the closed circles patients who did not have osteomalacia. The histological definition of osteomalacia was that given by the respective authors.

We feel that it is impossible to interpret an "abnormal" calcium infusion test and that the only possible value of the test is that a normal result may exclude osteomalacia.

Summary

A high retention of infused calcium has been regarded as evidence of osteomalacia. This extra retention has been attributed to the excess of uncalcified bone (osteoid). In 15 patients the calcium retention and the amount of osteoid were compared. Although eight patients with osteomalacia did have a high retention of infused calcium, so did four out of seven patients with a gastrectomy but without osteomalacia. There was no relation between the amount of calcium retained and the amount of osteoid. These findings, together with the reports of high retentions of infused calcium in bone disorders other than osteomalacia, make it impossible to interpret an "abnormal" calcium infusion test. It is suggested that the only possible value of this test is that a normal result may exclude osteomalacia.

We thank Miss Judith Metcalfe for technical help and the sisters and nursing staff of the Leeds General Infirmary for their willing co-operation.

The study owes much to the guidance of our chief, Professor Paul Fourman. The work was supported in part by a grant from the Medical Research Council to Professor Fourman.

Renal Papillary Necrosis in Sickle-cell Haemoglobinopathy

O. O. AKINKUGBE,* D.PHIL., M.B., M.R.C.P.ED.

Brit. med. J., 1967, 3, 283–284

Abel and Brown (1948) first drew attention to profuse haematuria in sickle-cell anaemia. Subsequent reports have confirmed that this association is more than fortuitous (Harrison and Harrison, 1952; Chapman *et al.*, 1955; Sharpe *et al.*, 1959). Haematuria is also known to occur in sickle-cell trait, sickle-cell haemoglobin C disease, sickle-cell thalassaemia, and a variety of combinations of haemoglobin S with other abnormal haemoglobins. The present report of four cases of haematuria in sickle-cell haemoglobinopathies is prompted for two reasons. Firstly, detection of blood in the urine of young adults in an environment endemic for schistosomiasis need not always indicate the presence of the infection. Of more practical importance is the surgical diagnostic problem sometimes posed by gross haematuria simulating renal neoplasm. Awareness of the possibility that this symptom may exist in sickle-cell haemoglobinopathy makes careful appraisal necessary, to avoid the inadvertent sacrifice of an apparently normal-functioning kidney.

Case 1

A 30-year-old female trader had had persistent haematuria for five weeks, at first mild, but later gross and alarming. There were no associated urinary findings. Her blood pressure (B.P.) was 120/85 mm. Hg. Both kidneys were easily felt. Her blood group was O-positive, sickling was present, and her genotype AS. The clotting-time (Biggs and Macfarlane, 1957) was 8 minutes and bleeding-time (Duke, 1910) 3 minutes. Haemoglobin (Hb) 7.3 g./100 ml.; packed-cell volume (P.C.V.) 22%; mean corpuscular haemoglobin concentration (M.C.H.C.) 33%; white blood count (W.B.C.) 6,600/cu. mm.; platelets 138,000/cu. mm. Her blood urea, electrolytes, and liver-function tests were all normal. Total serum proteins were 7.8 g./100 ml., and on electrophoresis showed a diffuse increase in the globulin fraction. Urinary specific gravity (S.G.) was 1008 and the specimen contained many red cells. At cystoscopy bleeding was observed from the left ureteric orifice. Intravenous pyelography (I.V.P.) showed good function bilaterally, but extending from three calices on the left was some contrast in small medullary cavities (Fig. 1). Her haematuria cleared gradually within a fortnight and she has since remained well and active.

Case 2

A tailor aged 47 was subject to recurrent episodes of painless haematuria for two months. Examination revealed severe anaemia (Hb 3.0 g./100 ml.). His urine contained a trace of albumin and its S.G. was 1006; red blood cells were detected at microscopy, but there were no casts. Blood group was O-positive, sickling was present, and his genotype AS. His blood urea was 16 mg./100 ml. Cystoscopy showed blood spurting from the left ureteric orifice. Left ureteric catheterization was followed by a retrograde pyelogram, after which a nephrectomy was performed. Naked-eye appearance of the kidney showed marked congestion of the vessels close to the papillae, with softening of the central and apical portions of the pyramid; there were blood clots in the renal pelvis. Microscopy did not reveal any abnormalities in either glomerular or tubular morphology. He remained well for five years, but has lately developed proteinuria and hypertension. The latter event has been complicated by congestive heart failure, but this has responded well to digoxin, thiazides, and reserpine. At the time of writing he remained practically symptom-free.

Case 3

A 37-year-old housewife gave a three-year history of recurrent attacks of haematuria, each episode lasting a few days. She had been so impressed by the transient nature of her symptom that she had not thought it necessary to seek medical attention. Indeed, all her previous admissions into hospital were for obstetric reasons, and during her last admission her ankles were noticed to be swollen, she had proteinuria and microscopic haematuria, and her B.P. was 140/100 mm. Hg. She was eventually delivered of a full-term live foetus, but at postnatal attendances these features persisted. Her red cells showed sickling, genotype AS. Blood-clotting and bleeding times were normal. Hb 11 g./100 ml.; P.C.V. 33%; M.C.H.C. 33%; W.B.C. 3,500/cu. mm. Her blood urea was 23 mg./100 ml. and total serum proteins were 8.0 g./100 ml. Urine: S.G. 1010; midstream sample contained a few red cells but numerous white cells. Culture of this yielded a mixed growth of coliform organisms, and a week's course of nitrofurantoin cleared her urinary infection. I.V.P. showed evidence of cavitation involving the central and apical parts of the right upper calicine configuration extending into the medulla.

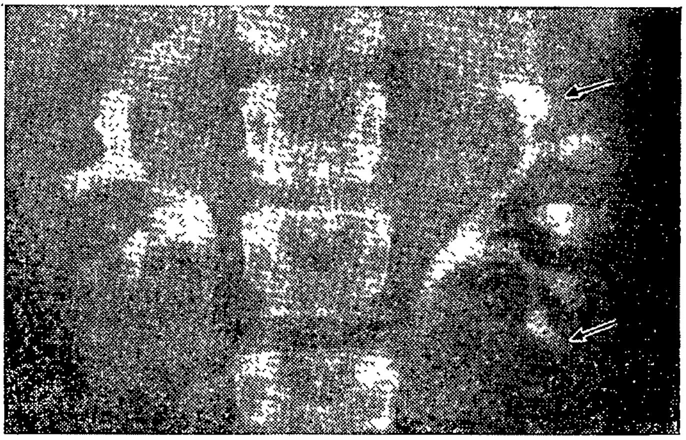

FIG. 1.—Case 1. Intravenous pyelogram (sickle-cell trait). On the left side dye extends from calices into small medullary cavities.

Case 4

A steward aged 37 had haematuria for two days. This was associated with frequency of micturition (three times at night), but there was no dysuria. Examination showed a well-built man with minimal pallor of his mucous membrane and tenderness in the right loin. B.P. 125/80 mm. Hg. Urine S.G. 1010, and midstream specimen contained many red cells and a trace of protein. His blood group was O-negative and genotype SS. I.V.P. showed changes in the right upper group of calices consistent with the medullary form of papillary necrosis (Fig. 2). Within a week his haematuria cleared completely and he has remained well for five years.

Discussion

Ischaemic infarction of the medullary pyramids has been known to occur since Friedreich's (1877) original description in a man with hydronephrosis due to an enlarged prostate. It was not until many decades afterwards (Günther, 1937) that its association with diabetes mellitus was recognized, becoming familiar to latter-day pathologists as necrotizing papillitis. In the past decade there have been widespread reports, notably from Switzerland and Scandinavia, of a great increase in the numbers of cases of renal papillary necrosis after excessive use of phenacetin compounds (Lindeneg *et al.*, 1959; Harvald, 1963).

---

* Lecturer in Medicine, University College Hospital, Ibadan, Nigeria.

It is estimated that about 4% of those individuals possessing the S gene suffer from haematuria at some time during their lives (Allen, 1964). Harrow *et al.* (1963) described renal papillary necrosis in five patients with sickle-cell trait. The true incidence of renal papillary necrosis in each of the various types of haemoglobinopathy is unknown. The scant reference in the literature to haematuria in patients homozygous for the S gene seems paradoxical, since the disorder is thought to be brought about by the presence of S haemoglobin. However, the relative frequency of this symptom in the trait may be more apparent than real. Firstly, the trait is far more common in the general population than the anaemia, and, secondly, the presence of haematuria as a lone symptom in the most innocuous of the genotypes naturally attracts more attention. The incidence of haematuria in haemoglobin SC disease is somewhere between these two extremes (River *et al.*, 1961).

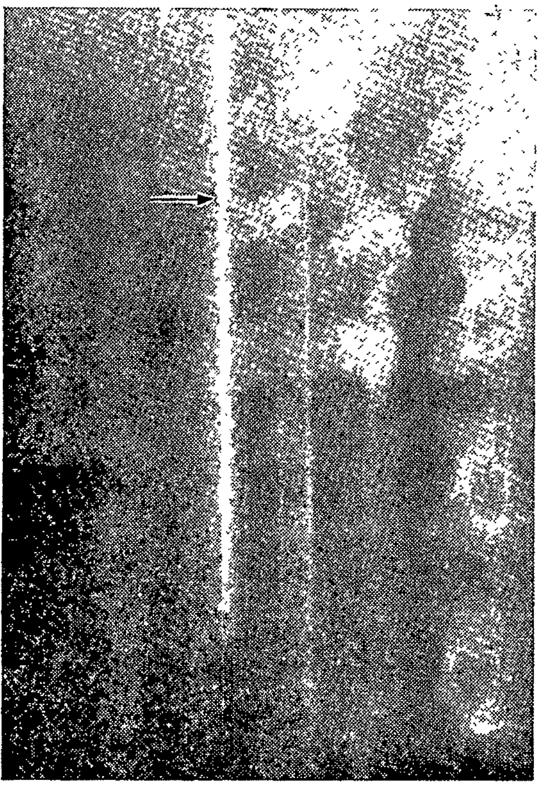

FIG. 2.—Case 4. Intravenous pyelogram (sickle-cell anaemia). On the right side the upper group of calices show changes consistent with papillary necrosis.

In more than half of all cases of papillary necrosis so far reported diagnosis was made during life by histological examination of papillae voided in the urine. Examination of renal biopsy specimens has not been rewarding. In three of the four cases reported above radiological investigation involving the use of contrast medium in I.V.P. revealed definitive ring changes in the renal papillae, formation of cavities in the pyramids or at the papillae, or an outline of concretions formed around necrotic fragments.

The pathogenesis of renal papillary necrosis in these states remains obscure. Its early association with diabetes and chronic obstructive renal disease suggested antecedent pyelonephritis. Support for this view was strengthened by the observation that phenacetin itself would cause an interstitial nephritis. The blood supply to the renal papillae derives from two sources: the vasa recta from the juxtamedullary region, and branches from the plexus of spiral vessels in the calix. Baker (1959) has shown how vulnerable these vessels are in diabetic arterial disease, infection, or back pressure on the calices. Whether primary vascular spasm occurs, as suggested by Kimmelstiel (1948), to account for ischaemic infarcts in sickle-cell crises is unknown. Perillie and Epstein (1961) found that sickling occurred in SS and AS subjects if the red blood cells were exposed to a hypertonic medium. It is well known that the counter-current system responsible for the concentration of urine produces a graded increase in osmolarity and lowering of oxygen tension from the base of the medulla to the tips of the papillae. It thus seems likely that increased viscosity and stasis would more readily affect the vasa recta supplying the papillary tips, leading to local ischaemia and tissue destruction.

Summary

Four cases of haematuria of varying severity associated with a sickling tendency are reported. Of these, three had sickle-cell trait and one sickle-cell anaemia. In three patients the radiological changes observed in the kidneys were those of renal papillary necrosis; in the remaining case the macroscopic appearance of the kidney from which the bleeding arose was suggestive of this lesion.

The conditions associated with renal papillary necrosis are reviewed. Hyperosmolarity in the region of the papillary tips is thought to predispose to sickling of red cells in neighbouring small vessels with subsequent ischaemic necrosis.

Preliminary Communications

A Serological Method for Demonstrating Recent Infection by Rubella Virus

Brit. med. J., 1967, 3, 285–286

Serological evidence of infection by rubella virus may be obtained by neutralization (Parkman *et al.*, 1964), complement-fixation (Sever *et al.*, 1965), or haemagglutination-inhibition tests (Steward *et al.*, 1967). As rubella often presents atypically or even inapparently, diagnosis on clinical grounds alone is liable to error. Because of the risk of subsequent congenital malformations (Gregg, 1941), serological tests are particularly valuable in the assessment of mothers exposed to or acquiring rubella early in pregnancy. Both neutralizing and haemagglutination-inhibiting (H.I.) antibodies often rise sharply to a high level early in the disease, a significant level of H.I. antibody sometimes being present on the first day of rash (Stewart *et al.*, 1967 ; A. Field, personal communication). In our experience many patients with rubella, particularly those who are pregnant, may be five to seven days or more from the onset of symptoms by the time they are referred for investigation. In these circumstances there may not be a significant rise in antibody titre between an acute phase sample of serum and a subsequent one taken two to three weeks later, both having equally elevated titres. This makes it impossible to say whether their antibody results from recent or from past infection. Although a rising or high complement-fixing antibody titre is useful, since it suggests relatively recent infection (Sever *et al.*, 1965 ; Schmidt and Lennette, 1966), a significant rise in antibody titre may not become detectable until four to six weeks after onset of symptoms (Sever *et al.*, 1966 ; Banatvala, unpublished observations), peak titres sometimes being achieved as late as three to six months after infection (Veronelli and Eckert, 1966).

The first immunoglobulins (IgM) to be detected after primary antigenic stimulus are of high molecular weight (Smith, 1960 ; Uhr and Finkelstein, 1963 ; Svehag and Mandel, 1964). These are almost entirely replaced within a few weeks by those of lower molecular weight (IgG and IgA). This paper describes a method of detecting the presence of recently acquired rubella antibody by H.I. tests, titrating early and late convalescent sera in parallel before and after treatment with 2-mercaptoethanol (2ME) ; this being a sulphydryl-reducing compound which breaks down IgM immunoglobulins.

MATERIALS AND METHODS

Serial serum samples were obtained from patients with rubella at variable intervals from the day of onset (day 1), to 14 months after illness. Sera showing elevated H.I. titres in acute (day 1–5), early convalescent (day 7–30), or late convalescent (6 weeks to 14 months) were pretreated with 25% kaolin and 50% day-old chick red blood cells according to the method described by Stewart *et al.*, 1967. Sulphydryl reduction was demonstrated by treating sera with 1/10 volume 0.5 *M* 2ME for one hour at 37° C. An equal volume of phosphate-buffered saline was added to untreated sera. Antibody titres were measured by H.I. tests (Stewart *et al.*, 1967), employing 8 HA units of ether-tween split virus antigen with a micro-titre apparatus and plastic disposable " V " plates (Linbro Ltd.). Treated and untreated sera were titrated in parallel. The results of most of these tests were confirmed with a double blind technique. Complement-fixing tests were performed with microtitre apparatus, employing overnight fixation at 4° C. with 1 unit of antigen (Flow Laboratories Ltd.) and 1.5 units of complement.

RESULTS

Eighteen (85.7%) of 21 sera obtained during the acute or early convalescent phase of illness showed consistent reductions in antibody titre after treatment with 2ME (Table I). The most marked reductions occurred in five sera (Cases 1–5) obtained during the first few days of illness (4 to 32-fold reductions) ; these included two sera obtained on the first day of rash. This suggests that even at this early stage true antibody consisting principally of IgM immunoglobulin is present. Thirteen (76.5%) of the 17 sera obtained in the early convalescent phase of illness showed consistent reductions in antibody titre, mostly twofold, but on two occasions fourfold in magnitude. However, of nine sera containing antibody to rubella virus collected during the first 14 days after the onset of illness, all showed reductions in antibody titre. The four early convalescent sera which were not reduced were obtained later, on days 16, 21, 23, and 27 respectively. A fourfold or greater rise in complement-fixing antibody between acute and early convalescent sera occurred in only 7 of 16 (43.7%) sera tested (Table I), although a twofold or greater rise was present in 14. Repeated tests on 14 late convalescent sera obtained from 11 patients failed to show reduction in antibody titre between treated and untreated sera (Table II), although complement-fixing antibody titres persisted or increased. Thus reductions in antibody titre after treatment with 2ME indicated that infec-

tion had occurred recently, whereas no reduction in antibody titre was suggestive, but was not conclusive evidence of less recent infection.

DISCUSSION

These results are similar to those obtained by Schluederberg (1965), who found consistent twofold to fourfold reductions in antibody titre after treatment with 2ME in serum obtained at 12-day to 21-day intervals after measles vaccination and natural infection with mumps virus, but no reduction in those obtained two months or more after infection. Lindquist *et al.* (1965), employing neutralization tests, observed fourfold or greater reductions in rubella antibody titre in seven of nine infants aged 10 weeks or less with the rubella syndrome, suggesting that, in addition to maternal IgG immunoglobulins, infants were synthesizing their own antibody, consisting principally of IgM components either before birth or in the neonatal period. Although treatment with 2ME provides a considerably less precise estimate of the presence of IgM immunoglobulins than, for example, analyses of antibody components by means of sucrose density gradients or gel filtration on Sephadex, the technique is simpler and can be used more readily if many sera have to be tested routinely. Even though the action of 2ME may not be entirely selective in breaking down only IgM immunoglobulins, both this and Schluederberg's series (1965) demonstrate that reduction in antibody titre after virus infection in early but not late convalescent sera, even though sometimes of small magnitude, is consistent. Reductions in antibody titre after treatment with 2ME compared favourably with complement-fixing tests as an index of recent infection by rubella virus. However, treatment with 2ME may be especially useful in assessing the duration of antibody in single serum samples obtained in the early stages of illness, a period at which greatest reductions in antibody titres are to be expected, or in obtaining evidence of recent infection in a proportion of patients who might present in early convalescence before complement-fixing antibody has fully developed. These preliminary results suggest that this test, since it can be both simply and rapidly performed, may, in conjunction with virus isolation and other serological tests, be of additional value in the assessment of patients who have been contacts of or who gave a history of rubella during pregnancy.

SUMMARY

Eighteen of 21 (85.7%) acute and early convalescent sera from patients with rubella showed reduction in haemagglutination-inhibiting antibody titre after treatment with 2ME, whereas all late convalescent sera showed no reduction. This test provided a method for recognizing recent infection by rubella virus that may be particularly useful in the serological assessment of mothers contracting rubella during pregnancy.

Medical Memoranda

Guillain-Barré Syndrome Associated with Chronic Lymphatic Leukaemia

Brit. med. J., 1967, **3**, 286–287

The occurrence of the Guillain–Barré syndrome in patients with chronic lymphatic leukaemia is rare. There seem to be no previous reports of this association, and it has been seen in only two instances in our series of more than 500 patients with chronic lymphatic leukaemia.

CASE 1

A man aged 60 was admitted to hospital at the end of November 1965 with a history of pain in the region of the right hip, radiating into the right thigh, accompanied by increasing weakness of the arms and legs. A diagnosis of chronic lymphatic leukaemia had been made in July 1965 after the examination of a peripheral blood smear and bone-marrow biopsy. He had been treated with chlorambucil.

On admission he was hardly able to walk. Fine movements with his hands were impossible. He was not anaemic, and there was no lymphadenopathy. His spleen was palpable 1 cm. below the left costal margin. He had generalized muscle weakness of his limbs and trunk. The muscles were flaccid ; there was no fasciculation but some tenderness, particularly of the leg muscles. All the tendon jerks were absent. The plantar reflexes were flexor. There was loss of appreciation of painful stimuli in a stocking and glove distribution. After admission he developed cranial nerve involvement, with a bilaterally symmetrical facial nerve weakness and some difficulty in swallowing.

Investigations.—The haemoglobin was 14.2 g. ; W.B.C. 15,200/cu. mm., with 11,400 lymphocytes ; E.S.R. 2 mm./hour (Westergren). The cerebrospinal fluid contained 58 mg. of protein per 100 ml. Porphyrins were not detected in the urine. Electromyography showed changes compatible with a widespread peripheral neuropathy, and a suggestion of primary muscle disease in the forearm muscles. The creatine kinase level was 0.3 unit. The serum protein contained a low level of gammaglobulin. The IgG was 720 mg./100 ml. IgM was 63% and IgA 23% of a reference normal serum.

Large doses of corticosteroid (60 mg. of prednisolone daily) brought slow but steady improvement. He was able to walk, and fine movements of his hands were possible. Electromyographic changes, still present, were compatible with a diagnosis of Guillain–Barré syndrome.

CASE 2

A woman aged 59 was admitted to hospital in October 1960 with a three-weeks history of pain in the back and left shoulder, and a steadily increasing weakness of her arms and legs. Four days before admission she had developed a bilateral facial weakness and difficulty in swallowing. A diagnosis of chronic lymphatic leukaemia had been made two years previously, in January 1958, as the result of examination of a blood film and bone-marrow biopsy. Some ten months before her present illness she had herpes zoster affecting the D 12 and L 1 dermatomes on the right side. She had been treated with a small dose of prednisolone for six months before the present illness.

On examination she was pale with scarring on her trunk following the attack of herpes zoster. There was no lymphadenopathy, but her spleen was palpable 1 cm. below the left costal margin. She had a bilaterally symmetrical facial palsy. Her arms were not weak, though her muscle tone was diminished and the tendon reflexes were much reduced. Her legs were weak, the muscles flaccid, and the tendon jerks much reduced. The plantar responses were flexor. Though she complained of subjective disturbances in sensation in the limbs there were no objective signs.

Investigations.—Haemoglobin was 10.7 g.; W.B.C. 84,000/cu. mm. (73,080 lymphocytes); E.S.R. 13 mm./hour (Westergren); platelets 140,000. Cerebrospinal fluid contained protein in a concentration of 320 mg./100 ml. with increased globulin and 66 lymphocytes/cu. mm. Diminished nerve conduction was demonstrated in the branches of the facial nerve. The serum proteins showed a low level of IgG, 720 mg./100 ml., and low levels of IgM and IgA, 23% and 6% of a reference normal serum respectively.

The patient was treated with 40 mg. of prednisolone daily and made a slow but steady recovery. Eight months later she was completely free from symptoms, and a year after her illness she had no abnormal neurological signs.

DISCUSSION

These cases show the usual clinical course of acute polyneuritis described by Guillain *et al.* (1916). Their progress contrasts with previous reports of polyneuritis complicating tumours of lymphoid tissue in which there has either been no recovery or only transient improvement. Williams *et al.* (1959) noted that peripheral neuropathy of some form occurred in only 2.25% of their series of 5,778 patients with lymphomas or leukaemias. The combination of chronic lymphatic leukaemia and peripheral neuropathy was seen in only three patients, and in none of these did it take the form of acute polyneuritis. The neuropathies described in their cases of lymphoma, and in single cases of reticulum-cell sarcoma (Blanchard, 1962) and lymphofollicular reticulosis (Shafar, 1965), resembled those seen in other malignant conditions, particularly carcinoma.

The association of diseases of the nervous system and those of lymphoid tissue occurs in such conditions as idiopathic autoimmune haemolytic anaemia, which may be complicated by peripheral neuritis, or in Hodgkin's disease and chronic lymphatic leukaemia where demyelinization occurs in the central nervous system (Åström *et al.*, 1958; Cavanagh *et al.*, 1959). In these instances it would seem likely that there was an immunological basis for the pathological changes. Widespread involvement of lymphatic tissue in infection may rarely be associated with peripheral nerve lesions. Infectious mononucleosis may sometimes be complicated in this way.

The cause of Guillain–Barré syndrome is uncertain—it may be immunological or infective in nature. The benefit that steroid therapy has on the course of the condition would suggest that there is an autoimmune process directed at damaging nervous tissue. Melnick and Flewett (1964), in reviewing the theories of causation, did not find evidence of a specific viral cause. They were, however, able to show, in a carefully controlled clinical study, that common viral infections were significantly more common in patients with Guillain–Barré syndrome than in a matched control population.

Heath *et al.* (1964) showed that the level of resting antibodies in a wide variety of virus infections was reduced in chronic lymphatic leukaemia, and the ability to form antibodies against influenza viruses grossly impaired. The level of globulin concerned with response to infection, IgG, was reduced in the two cases reported here, and this may have rendered them more susceptible to virus infections. If the polyneuritis is precipitated by a virus infection, then it would appear from these cases that the prognosis of the neurological lesion is not made worse by the chronic lymphatic leukaemia and associated hypogammaglobulinaemia. This would support the concept that the perpetuation is an autoimmune phenomenon.

We are grateful to Sir Ronald Bodley Scott for allowing us to publish these case reports, and for his helpful criticism and advice. Dr. Ann Beardwell kindly carried out the electromyographic studies, and the serum protein estimations were made with the helpful co-operation of Dr. D. S. Rowe.

Gas in the Portal Vein in Association with a Pelvic Abscess

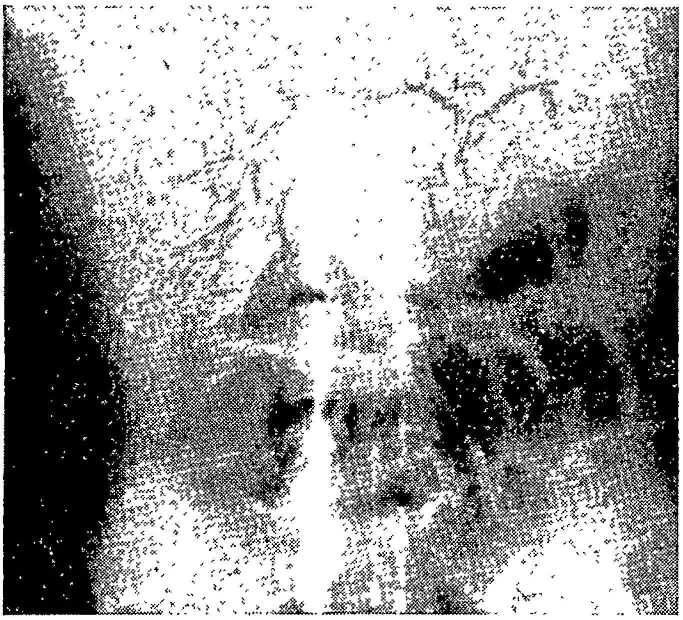
Brit. med. J., 1967, 3, 288

The radiological demonstration of gas in the portal vein was first reported by Wolfe and Evans (1955), and since then there have been nine further papers on this subject in the English language (Susman and Senturia, 1960 ; Sisk, 1961 ; Wiot and Felson, 1961 ; Barrett, 1962 ; Stewart, 1963 ; Guyer and Grainger, 1963 ; McCandless, 1964 ; Lazar, 1965 ; Fink and Boyden, 1966). The purpose of this communication is to record a further example of this apparently rare finding, which occurred in association with a pelvic abscess, and briefly to review the literature.

CASE REPORT

A 49-year-old woman was referred in 1964 with a rectovaginal fistula complicating radium therapy for carcinoma of the cervix in 1950. A loop sigmoid colostomy had been constructed in 1951 and was working satisfactorily, but the patient wished to be rid of it. Accordingly, it was decided to resect the fistula and the affected segment of rectum by an abdomino-anal pull-through excision. This was done in November 1964 under cover of the existing colostomy. Her postoperative course was complicated by pulmonary atelectasis and infection, which responded only slowly to physiotherapy and antibiotics, and delayed the closure of the sigmoid colostomy until 29 March 1965. After this procedure atelectasis recurred with infection and she was given a course of penicillin and streptomycin, which may well have masked the development of a pelvic abscess. However, she seemed to make good progress and was discharged home on the fourteenth postoperative day. She was readmitted three days later with abdominal distension and cardiovascular shock due to a bowel obstruction. After resuscitation plain abdominal *x*-ray examination was carried out in the erect and supine positions, and showed the following features: (1) moderate small-bowel distension with fluid levels ; (2) a fluid level in the pelvis, apparently in a well-defined cavity, suggesting a high pelvic abscess ; and (3) linear gas shadows in the liver extending to within 2 cm. of the liver margin, as occurs when gas is present in the portal vein and its branches (see Fig.).

Laparotomy was performed on the day of admission and confirmed the diagnosis of a small-bowel obstruction, this being due to adhesions between the small bowel and the wall of a pelvic abscess closely related to the site of colostomy closure. The bowel was only moderately distended and there was no evidence of ischaemia. The adhesions were freed and the abscess was drained. At the conclusion of the operation a tracheostomy was performed because of the previous episodes of postoperative pulmonary collapse and infection. Bacteriological culture of the pus obtained from the pelvic abscess gave a heavy growth of a coliform organism. During the operation the patient was given tetracycline, because, despite apparently adequate fluid and electrolyte replacement, her general condition deteriorated and it seemed likely that the abdominal condition was complicated by a Gram-negative septicaemia, though we were not able to prove this by positive blood culture. Her condition improved and she was subsequently treated in the intensive-care ward. Her initial progress was satisfactory and bowel function was re-established. Antibiotic therapy was changed from tetracycline to ampicillin on the basis of sensitivity tests. A pulmonary infarct was revealed radiologically on the seventh postoperative day, and this was complicated by a pyopneumothorax on the ninth day. Intercostal suction-tube drainage was instituted and chloramphenicol added to the antibiotic regimen, but she slowly deteriorated and died on the eighteenth postoperative day. Permission for necropsy was refused.



Supine abdominal *x*-ray plate of patient, showing moderate small-bowel distension and the portal veins outlined by gas. Note the gas shadows approach to within 2 cm. of the liver margin, a feature which serves to distinguish this variety of intrahepatic gas from the more commonly occurring condition of gas in the bile-duct system.

Throughout the postoperative period daily *x*-ray plates of her chest and abdomen were obtained, but in none of these was gas demonstrated within the hepatic shadow.

COMMENT

Gas in the portal vein is a rare finding, probably owing to its transient nature and to difficulty in obtaining good quality *x*-ray films in severely ill patients. When obtainable, however, the radiological features are characteristic (see Fig.). An analysis of the pathology in 29 reported cases (see Table) emphasizes the combination of gross distension and impaired viability of the bowel. These features were noted in no fewer than 26 of the 29 cases. Susman and Senturia (1960) suggested three possible sources of gas in the portal vein: (1) gas within the distended bowel ; (2) gas-forming organisms within the bowel wall ; and (3) gas from an abscess cavity within the drainage area of the portal vein. In most reported cases the first two of these factors seem to be implicated in that the bowel was distended and ischaemic. Portal septicaemia may well be an accompanying feature, and in one reported case (Barrett, 1962) a positive blood culture for gas-gangrene organisms was obtained at operation from the portal vein.

Pathological Lesions Present in 29 Recorded Cases of Gas in the Portal Vein

Vascular occlusions:	
(*a*) Thrombosis or embolism of superior mesenteric artery or vein	10
(*b*) Strangulation of bowel	3
Necrotizing inflammations of intestine	7
Inflammation with less definite necrosis	6
Severe mediastinitis with septicaemia	1
Diabetic acidosis with bowel distension	1
Pelvic abscess with intestinal obstruction	1

Bowel distension was present in 27 patients, this distension often being described as gross or very marked. Impairment of the viability or actual necrosis of the intestinal wall was present in 26 patients.

The present case is unique in that gas in the portal vein was associated with a proved intra-abdominal abscess containing gas, which may well have been forced into the portal venous system. However, even in this patient portal septicaemia has not been excluded as a contributory factor.

I am grateful to Professor J. C. Goligher for permission to publish this report and for his helpful advice in the preparation of the paper.

Current Practice

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Mechanism of Leuco-erythroblastosis

Q.—*What is the mechanism of leuco-erythroblastosis in the bone-marrow replacement syndrome?*

A.—The term "leuco-erythroblastic anaemia" was defined by Janet Vaughan[1] as a condition characterized by the presence in the peripheral blood of immature red cells and a few immature white cells of the myeloid series. She noted its association with infiltrative bone marrow disease. Subsequently the term "leuco-erythroblastosis" came into use in recognition of the fact that anaemia may be disproportionately slight or even absent.

The most common cause is infiltration of bone marrow by carcinoma, and it also occurs when the bone marrow is infiltrated by other foreign cells, such as in myelomatosis, myelosclerosis, and xanthomatosis, and also when there is overgrowth of the bony tissue itself, as in osteopetrosis. It should not be forgotten, however, that leuco-erythroblastosis does not necessarily imply marrow infiltration. It also occurs in association with haemolytic anaemias, severe bacterial infections, and a group of miscellaneous conditions including liver disease.[2]

With such a wide range of causes the mechanism of the leuco-erythroblastosis is unlikely to be due to a single factor. The question refers especially to the bone-marrow replacement syndrome, but even here the problem is a complex one. The traditional explanation is that the infiltrating foreign material causes "irritation" or "stimulation" of adjacent marrow leading to excessive myeloid and erythroid activity. This is a facile explanation, which does not really clarify the problem. When there is an infiltrative tumour the presence of leuco-erythroblastic anaemia does not mean that the bone marrow has been crowded out by the tumour tissue.

There seems no quantitative relationship between the extent of infiltration and the leuco-erythroblastic reaction.[3] It is possible that tumour cells produce some chemical factor which leads to marrow hypofunction and premature release of some cells into the circulation, or they may have an effect by diverting some haematinic factor necessary for normal maturation. Erythropoietin promotes differentiation of the erythroid stem cell into the erythroblast with subsequent release of newly formed mature cells into circulation. A block in the production of erythropoietin and the equivalent leucocyte factor or interference with their sites of action by neoplastic disease, either in the bone marrow or at the primary site of the tumour, have been postulated.[3]

Another suggestion has been that stress or damage to bone marrow as a result of the infiltration leads to the evolution of areas of extramedullary haematopoiesis, and that the immature circulating cells are derived from these sites where the barriers which restrain the release of immature cells are not as effective as in the bone marrow.[4] However, the mechanism by which the foci might develop is not clear, especially when anaemia is slight, and it is again necessary to postulate tumour stimulus on the haematopoietic regulators.

The short answer to the question is that the mechanism is unknown.

Oral Contraceptives and Fertility

Q.—*For how long should a course of oral contraceptives be given to try to increase fertility, and which preparation would be best for this purpose?*

A.—Though there is some evidence that a "rebound phenomenon" occurs after discontinuing oral contraception and that some women are more likely to conceive, I know of no way of predicting in which patient it is likely to happen.

I assume that both partners have had full-scale infertility investigations and no abnormalities have been discovered in either. I would not, under these circumstances, use oral contraception to initiate a rebound phenomenon. If however anovulation has been demonstrated, treatment is best effected in suitable cases by the use of either clomiphene citrate or human pituitary gonadotrophin.

Subarachnoid Haemorrhage

Q.—*Is there any firm evidence of an association between subarachnoid haemorrhage and a chronic cough?*

A.—There is no evidence of any association in terms of pathology or aetiology between subarachnoid haemorrhage on the one hand and conditions causing chronic cough on the other.

It is plain that coughing causes increased pressure in the venous system which is in turn communicated to the intracranial venous sinuses, so that each cough causes a transient rise in intracranial pressure. This increased pressure is, however, venous, though it is communicated to the cerebrospinal fluid, and there is no convincing evidence that intra-arterial pressure is significantly raised during the act of coughing. In fact, repeated coughing may cause it to fall sharply, as in the syndrome of cough syncope.

These points are raised since it is apparent that there are many recorded instances in which subarachnoid haemorrhage has followed physical exertion or trauma of many kinds, but almost invariably the mechanism implicated has been one which would be expected to raise intra-arterial pressure. Despite this common association, most authors now believe that exertion simply precipitates rupture of an aneurysm or vascular malformation which was about to rupture spontaneously, since most subarachnoid haemorrhages occur during rest and many have been observed to begin during sleep.

There is no statistical relationship between intracranial aneurysm and angioma on the one hand and any lung disease on the other, though very rare instances of subarachnoid haemorrhage have been described as a complication of tuberculous meningitis resulting presumably from tuberculous arteritis in intracranial vessels, and equally rarely subarachnoid haemorrhage has been shown pathologically to be due to the presence of cerebral metastases from bronchial carcinoma.

Salk Vaccine as Booster

Q.—*Is oral poliomyelitis vaccine the best to give as a booster immunization in adolescents who were immunized with Salk vaccine in childhood?*

A.—Yes, it is the best. Whereas another injection of Salk vaccine would boost the poliomyelitis antibody titres, a similar effect is obtained by the administration of the oral vaccine. The oral vaccine also produces intestinal immunity to polioviruses and provides a more durable protection.

The main disadvantages of oral vaccine as a booster after a primary immunization course with Salk vaccine is that a single administration may not always be effective against all the three types of polioviruses. It is therefore desirable to give a second dose of oral vaccine not less than four weeks after the first.

Book Reviews

Medical Virology

Modern Trends in Medical Virology—1. Edited by R. B. Heath, M.D., and A. P. Waterson, M.D., M.R.C.P. (Pp. 231+viii; illustrated. 65s.) London: Butterworth. 1967.

The "Modern Trends" series have been bringing us articles on recent developments in microbiology for some years, but this is the first of the series to be devoted to medical virology. The editors have chosen well in their ten authors from Great Britain, the United States, Sweden, and Germany, who have reviewed developments of the greatest interest in the subject.

Though many chapters and books have been written on the nucleic acids of viruses, few are as concise and well documented as Burke's contribution to this volume. Rott and Scholtissek have used the work on myxoviruses to review many of the concepts of virus cell interaction. In the chapters by Bauer on antiviral chemotherapy and Baron on host defences during virus infection it is significant that a quarter of the book is devoted to body defence by humoral and cellular mechanisms. Dudgeon has given a clear and up-to-the-minute review of the recent knowledge of rubella at the clinical and laboratory levels, and Morley has discussed the medical and economic aspects of measles immunization, especially in the developing countries.

In the last three or four years we have heard much about the 31 serotypes of adenoviruses, and it is useful to have their importance in diseases of the intestinal tract reviewed by Potter. It is equally important to read such an authoritative opinion on the relationship between cytomegaloviruses and herpes viruses as that of Plummer. The final chapter, on immunology of virus-induced tumours, covers a rapidly changing field and has been well summarized by Sjögren.

This is a very readable book that will have an interest to both the senior student and research worker. Though at the price few will consider it a necessary addition to their personal collection, no science library can afford to be without it.

F. T. PERKINS.

Growth of Thought

The Art of the Soluble. By P. B. Medawar, F.R.S. (Pp. 160. 25s.) London: Methuen. 1967.

This collection of six essays and addresses and two book reviews centres round the nature of scientific discoveries and the kind of men who make them. They are beautifully written in lucid, lively prose and display the penetrating insight and immense learning we should expect from their distinguished author.

The first, *D'Arcy Thompson and Growth and Form,* is a deeply appreciative and critical appraisal of a man and his work. It begins: "D'Arcy Wentworth Thompson was an aristocrat of learning whose intellectual endowments are not likely ever again to be combined within one man. He was a classicist of sufficient distinction to have become President of the Classical Associations of England and Wales and of Scotland; a mathematician good enough to have had an entirely mathematical paper accepted for publication by the Royal Society; and a naturalist who held important chairs for sixty-four years, that is, for all but the length of time into which we must nowadays squeeze the whole of our lives from birth until professional retirement. He was a famous conversationalist and lecturer (the two are often thought to go together, but seldom do), and the author of a work which, considered as literature, is the equal of anything of Pater's or Logan Pearsall Smith's in its complete mastery of the *bel canto* style. Add to all this that he was over six feet tall, with the build and carriage of a Viking and with the pride of bearing that comes from good looks known to be possessed."

The second, *Herbert Spencer and the Law of General Evolution,* contains this: "In our moods of abstract theorization we tend to forget how great and how diverse are the functional commitments of biological macromolecules. They insulate, they fill out; they fetch and carry; they prevent the Organism as a whole from falling apart or from dissolving in water; they prop up, they protect; they attack and defend; they store energy and catalyze its transfer; they store information and convey messages, and sometimes they themselves *are* messages. The successful prosecution of all these activities depends upon properties more complex, various and particular than can be written down in the language of energetics or information theory." It ends: "But for all that, I for one can still see Spencer's System as a great adventure, and now that I know my way about those thick, square volumes I do not feel I am taking leave of them for good."

Darwin's Illness. "Before I began I had no idea of what treasures of nonsense I should find in the psychoanalytical literature."

The Phenomenon of Man. "A good deal of Teilhard is nonsense, but on further reflection I see it as a dotty, euphoristic kind of nonsense, very greatly preferable to solemn long-faced germanic nonsense."

The Act of Creation. "Like other amateurs, Koestler finds it difficult to understand why scientists seem so often to shirk the study of really fundamental or challenging problems." "The real reason is so much simpler; the problem is very, very difficult." "No scientist is admired for failing in the attempt to solve problems that lie beyond his competence. The most he can hope for is the kindly contempt earned by the Utopian politician. If politics is the art of the possible, research is surely the art of the soluble. Both are immensely practical-minded affairs."

A Biological Retrospect. "However, if complacency is to be deplored, so also is humility. Humility is not a state of mind conducive to the advancement of learning. No one formula will satisfy that purpose, for there is no one kind of scientist; but a certain mixture of confidence and restless dissatisfaction will be an ingredient of most formulae. Confident we may surely be, for the next twenty-five years will throw up many new ideas as profound and astonishing as any I have yet described, namely . . . but I have no time left to tell you what they are."

Two Conceptions of Science. "My theme is popular misconceptions of scientific thought. I shall argue that the ideas of the educated lay public on the nature of scientific inquiry and the intellectual character of those who carry it out are in a state of dignified, but yet utter, confusion. Most of these misconceptions are harmless enough, but some are mischievous, and all help to estrange the sciences from the humanities and the so-called 'pure' sciences from the applied."

Hypothesis and Imagination. "We may collect and classify facts, we may marvel at curiosities and idly wonder what accounts for them, but the activity that is characteristically scientific begins with an explanatory conjecture which at once becomes the subject of an energetic critical analysis."

The questions asked in this book are simple, but they are never superficial and not often entirely solved. I hope it will have an influence similar to that of *Growth and Form*: "It is to be seen in anyone who, having read it, tries to write a little more clearly and with at least an attempt at grace; or who realizes, perhaps for the first time as he turns its pages, that science cannot be divided into what is up to date and what is merely of antiquarian interest, but is to be regarded as the product of a growth of thought."

GEORGE PICKERING.

Nocturnal Enuresis

A New Approach to Nocturnal Enuresis. By C. R. A. Martin, M.B., B.S.(Lond.), D.P.H., L.R.C.P., M.R.C.S., F.R.S.H., D.P.A., Inter.LL.B. (Pp. 149+viii; illustrated. £1 2s. 6d.) London: H. K. Lewis. 1966.

The author presents a comprehensive review of nocturnal enuresis based on a painstaking survey of several thousand schoolchildren from the Birmingham area. Medical examinations were carried out as a routine at 5–6 years (on school entrance), at 10–11 years (on leaving primary school), and at 14–15 years (on school-leaving), and provided suitable opportunity for inquiry. Interesting figures are given for primary and acquired enuresis in the two sexes at different ages and the apparent influence of social and domestic circumstances. The effect of physical and psychological factors is briefly discussed, and particular reference is made to the role of hypersomnia and nocturnal polyuria.

After outlining the pattern of the disability the author turns to the subject of treatment. This is considered in two parts, the former embracing what may be termed conventional methods, including training, wet-bed "buzzers," a variety of drugs, and psychotherapy, and a subsequent chapter devoted to nocturnal antidiuretics. The latter clearly represent a major interest, which indeed affords the main justification for the title of the book. Based on the premise that some cases of enuresis are caused by a reduced secretion of antidiuretic hormone by the pituitary, treatment with vasopressin was given to a small series of otherwise intractable children, with encouraging results. As the author points out, the indications and scope for such treatment are difficult to assess, since, although an excess of A.D.H. can be reliably measured, subnormal secretion cannot easily be defined. Nevertheless, if further studies confirm that sustained improvement occurs when treatment is prescribed purely on empirical grounds, a considerable advance will have been made in the management of this distressing disability for which many will be grateful.

The book should appeal to all practitioners and those in charge of paediatric clinics to whom such cases are referred.

J. D. Fergusson.

Calcium and Bone

Calcium Metabolism and Bone Disease. A Textbook for Students and Practitioners. By W. P. U. Jackson, M.A., M.D., F.R.C.P., D.C.H. (Pp. 134; illustrated. 30s.) London: Edward Arnold. 1967.

The declared purposes of this book are to show that the study of calcium metabolism and metabolic bone disease is not as difficult as usually imagined, and to provide a text suitable for both medical students and those specialists who are concerned with these subjects—namely the urologist, orthopaedic surgeon, and paediatrician. In order to achieve these objects Dr. Jackson has used the concise but informal style of the seminar. This has enabled him to pack a tremendous amount of up-to-date information into a small number of pages without loss of clarity and without degenerating into a mass of indigestible facts.

The main figures and radiographs are clear and helpful. For such advantages, however, a price has had to be paid, and it is inevitable that many dogmatic statements are made on matters which are still the subject of much debate by the experts. Furthermore, no references are given and therefore the book cannot be taken as an authoritative work for use by the expert in the field. It must be said, however, that with one or two exceptions, noted below, the statements made fairly represent the opinions of the majority of the experts at the present time; also there are suggestions for further reading at the end of each chapter. The book will therefore hold considerable appeal to those for whom it was intended and it can be highly recommended for them.

All of the common, as well as some of the rare, metabolic diseases are well described. There are many helpful hints which reflect the author's considerable experience in this field. A surprising omission is the failure to describe the radiological differences between the spines of osteoporosis and osteomalacia. Two curious departures from orthodoxy require comment. First the impression is given that hypercalcaemia is a more important factor in causation of renal calculi than is hypercalciuria. Secondly, it is rather misleading to suggest that 3 parts per million of fluoride in drinking-water is harmful, since higher levels are required before any abnormalities are visible to the naked eye. These are small points of detail, however, and they do not detract from the overall value of the book.

G. A. Rose.

Operative Surgery

Textbook on Operative Surgery. 3rd edition. By Eric L. Farquharson, M.D., F.R.C.S.Ed., F.R.C.S. (Pp. 951+viii; illustrated. £6 6s.) Edinburgh and London: E. & S. Livingstone. 1966.

This book is now appearing in its third edition, and this alone is an indication that there is still a considerable demand for the one-author, one-volume textbook on operative surgery written by a general surgeon. The author states that he has endeavoured to describe in detail and with adequate illustrations those operations which a junior in general surgery might be required to perform or in which he might assist. This is a heavy task but one in which the author seems to have succeeded.

The book has been brought up to date, and several sections have been rewritten. In general the illustrations are good and there are some excellent accounts of surgical anatomy where it is especially felt to be required. In treatment the author follows the standard teaching, but occasionally he expresses his own views if they do not coincide, and this increases the interest for the reader. Occasionally an operation now less commonly used appears to be given undue prominence, or one favoured by the reader receives brief mention. This can hardly be otherwise and does not detract from the fact that this is an excellent book for those who are learning their surgery.

E. G. Muir.

Science in Medicine

The Scientific Basis of Medicine. Annual Reviews. 1967. British Postgraduate Medical Federation. (Pp. 382+ix; illustrated. 40s.) London: Athlone Press. 1967.

This volume contains twenty review articles based on the weekly open lectures arranged by the British Postgraduate Medical Federation. They were delivered between October 1965 and March 1966 and constitute the fifteenth annual series.

Osler said, "As is your pathology so is your medicine," and nowhere is that better illustrated than in these fascinating vignettes of a wide range of problems in the science of disease. That there is such a thing as the "art of medicine" is undeniable, but it is increasingly clear that the quality of the prevention, diagnosis, and cure of disease is absolutely dependent on fundamental and applied science. A doctor without science is as useless as a mariner without navigation. Every act of therapy should be an experiment. Such is the clear message of those penetrating articles.

It is very appropriate that the opening review by Sir George Godber should survey in a masterly way the impact of scientific discovery on the pattern of medical care and the implications this has on the organization of our National Health Service.

Nearly half the reviews come under the broad classification of cellular biology, and deal with such topical subjects as the immunological reaction of the cell surface by R. R. A. Coombs and the role of the mycoplasmas in human disease by D. G. ff. Edward. The reviewer found the account of immunological sympathectomy by Eleanor Zaimis particularly interesting. She traces the steps in the discovery of the nerve growth factor which is produced by mesenchymal cells, and the further discovery that the factor is immunologically competent and its antisera can prevent the development of the adrenergic nervous system in rats. This opens up a wide range of studies which are enlarging knowledge of the sympathetic nerves in homoeostasis.

In the field of clinical science the account by J. P. Shillingford of the haemodynamic effects of acute myocardial infarction is of the utmost importance in relation to the control of this dangerous disease. These life-saving procedures provide an answer to those who are inclined to regard the use of the "cardiac catheter" as unjustifiable experimentation.

The few reviews mentioned are selected at random to show the uniform excellence of the whole series. All doctors still interested in their work should make a point of reading this volume.

Temporal Lobe Epilepsy

Biological Factors in Temporal Lobe Epilepsy. Clinics in Developmental Medicine No. 22. By Christopher Ounsted, Janet Lindsay, and Ronald Norman. (Pp. 135; illustrated. 21s.) London: William Heinemann. 1966.

This monograph discusses the problem of "temporal lobe epilepsy" from a viewpoint different from most of the publications on this controversial subject. The authors have made a detailed study of 100 children suffering from this condition attending the Park Hospital for Children at Oxford. Some of these children were under observation before they developed temporal lobe seizures.

There is a detailed analysis of many aspects of these children—for example, family history, birth weight, the occurrence of febrile convulsions, the age of onset of temporal lobe seizures, etc. The chapters on "the hyperkinetic syndrome" and on "catastrophic rage" are particularly valuable, although these phenomena are not confined to children with temporal lobe attacks or indeed to children suffering from any type of epilepsy. The authors, supported by pathological study of several cases, place considerable emphasis on status epilepticus and severe febrile convulsions as a cause of damage to the hippocampus and amygdaloid nucleus with the subsequent development of temporal lobe epilepsy. They stress the importance of this post-epileptic encephalopathy and the urgent need to control intracranial infections in infants and febrile convulsions as quickly as possible.

This monograph is of real value and should interest everyone concerned with the pathogenesis of epilepsy.

J. W. ALDREN TURNER.

Disputed Aetiology of Lung Cancer

Occupational and Environmental Cancers of the Respiratory System. By W. C. Hueper. (Pp. 214+xi; illustrated. DM. 34.) Berlin, Heidelberg, and New York. Springer. 1966.

Dr. W. C. Hueper is a distinguished American authority on cancer in its various aspects, and his new book *Occupational and Environmental Cancers of the Respiratory System* will be unpopular with those who hold that almost the only cause of lung cancer is the smoking of cigarettes. He has assembled an impressive body of evidence which shows that the occupational and environmental causes are of equal if not more importance. He says that the role of the cigarette has been studied comprehensively by numerous investigators, whereas very modest efforts have been made to obtain pertinent information about the occupational and environmental carcinogens. These he claims have considerably more potency than cigarette smoke, but also have more prolonged and intense contact with large portions of the general population. This disproportionate attention to cigarettes has produced a distorted assessment of the relative significance of the various carcinogens, and has interfered with an effective approach to preventive measures against respiratory cancer hazards of all types.

That there are many occupational and environmental respiratory carcinogens is undoubted. Dr. Hueper divides them into three categories: recognized, suspected, and potential. The recognized carcinogens include the inorganic arsenicals, asbestos, chromates and chrome pigments, nickel, isopropyl oil, mustard gas, mineral oil, coal tar, and radioactive substances. The suspected group contains beryllium, benzidine, iron oxide, soot—that is, incomplete combustion products of carbon, petroleum, wood, and gas; the chemicals contained in gasoline and diesel engine exhausts, as well as the thermic tobacco derivatives. The potential respiratory carcinogens are those agents for which the incriminating evidence is predominantly restricted to observations made in experimental animals. This group includes carbamates, nitrosamines, isoniazid, carbon polymers, and the oxidized aliphatic and aromatic hydrocarbons generated in heated vegetable oils and animal fats and by photo-oxidation of evaporated gasoline.

Dr. Hueper says that existing epidemiological information about occupational lung cancer is restricted to data obtained from surveys of relatively small industrial operations with excessive respiratory cancer risks. No country possesses any large-scale and systematized information on the position in large industries where carcinogens are produced or handled and in which many thousands of people are employed. The large American industries of this type include the iron and steel industries, the power industry, petroleum industry, metal ore smelting and refining industries, metallurgical industries, chemical, rubber, and plastic industries, asbestos industry, transportation, shipping, railroad, and aviation, and also the paper and textile industries. Even when fragmentary epidemiological data do exist, they seldom cover the workers who have left the hazardous occupations. Rarely any attempt has been made to ascertain the number of occupational respiratory cancers which occurred before the discovery of a cancer risk in an industry. It is, he says, intriguing to speculate about the number of cases of lung cancer which were elicited in chromate workers in a plant which at the time of the discovery of the hazard showed a lung cancer frequency of 40 times the standard rate amongst white workers and 80 times amongst coloured workers, considering the fact that this plant had been engaged on the production of chromates for over five decades. " It is also provocative to contemplate the medical diagnosis of the cause of death for workers dying from a pulmonary complaint after being employed in an asbestos brake-lining factory, before it was found on post-mortem examination of such workers that 50% of those who came to autopsy with the diagnosis of asbestosis, were also suffering from cancer of the lung."

The information which Dr. Hueper has collected shows that lung cancer rates in various parts of the world vary according to social class and income-bracket, the poorer members of most communities being most affected and that the rates vary greatly between one occupation and another. Further, they are higher in urbanized than in agricultural communities. He comments that such fluctuations in the liability to lung cancer among such diverse groups cannot justly be attributed to differences in constitutional susceptibility to cancer. They can be ascribed, he thinks, only to quantitative and qualitative variations in exposure to environmental and occupational respiratory carcinogens, some of which are not yet identified. There is no evidence, he says, that such variations in lung cancer frequencies for different worker groups are in any way causally associated with demographic differences in cigarette-smoking habits. Again this factor is not responsible for the high incidence of lung cancer in women working in smoke-filled kitchens or inhaling smoke from braziers, such as Mexican women in Southern California or the Bantu women in South Africa.

He points out that air pollution containing respiratory carcinogens causes a shift of the incidence of lung cancer to earlier ages, and he cites figures showing the high liability to lung cancer of British immigrants to New Zealand, South Africa, and the United States. He regards the age shift of lung cancer to younger English people as the result of a progressively intensified exposure of the children of England to carcinogenic air pollutants.

Whether one agrees or not with Dr. Hueper's interpretation of the detailed information which he has collected, it cannot be denied that his book is an important one, and that he is justified in quoting with some disdain a recent comment by a high medical official of the United States Public Health Service that as regards lung cancer risks from cigarettes no more research is necessary for the establishment of the facts. Dr. Hueper clearly believes that the occupational and environmental causes are more important.

A. I. G. McLAUGHLIN.

Clinicopathological Conference

A Case of Diarrhoea and Goitre

DEMONSTRATED AT THE ROYAL POSTGRADUATE MEDICAL SCHOOL

Clinical History

Dr. C. L. Cope: The patient (Case No. 242467; P.M. No. 11630) to be considered today was a retired Greek-Cypriot government servant, born in 1898. His mother was still alive at the age of 89 but had an enlarged thyroid and a tendency to diarrhoea. His wife and three brothers were alive and well, but his father had died at the age of 61 with congestive heart failure.

The patient was first seen at Hammersmith Hospital in August 1960 when he was admitted for bilateral herniorrhaphy. He was in hospital for 14 days. His cervical spine was reported to be scoliotic but no mention was made of a goitre.

In November 1960 he was seen at Hammersmith Hospital as an outpatient because of a 10-year history of diarrhoea. He was noted to have a large nodule in the thyroid gland, which displaced the trachea to the left. It was considered clinically to be non-toxic. Barium follow-through and barium enema were normal except for a few diverticula in the colon. There was a long-standing story of mild dysuria, but his return to Cyprus prevented further investigations.

In March 1962 amoebiasis was diagnosed in Cyprus and he was treated with emetine and stovarsol. His stools were reported to contain pus and red cells and the cysts of *Entamoeba histolytica*. In spite of this treatment he continued to have three to eight motions each day.

In March 1963 he returned to England and in June of that year he was readmitted to Hammersmith Hospital.

His complaint was that he had lost 7 kg. weight in the past two years, that he was easily tired, and that his stools were watery and pale, though without blood and not bulky. There was no dysphagia and no symptoms of thyrotoxicosis. The goitre, he thought, had been present for about four years, but had shown no evident growth in the last two years. There had been no episodes of symptoms of cardiovascular abnormalities and no paraesthesiae, headaches, or attacks of pallor. There was no history of flushing.

On examination his weight was 53 kg. He had a dorsal kyphoscoliosis. There was no skin abnormality, and no fibromata or café-au-lait spots. His pulse was 100 and blood pressure 130/80 mm Hg. The sleeping pulse was at first 100, but this fell to 80 in a few days. There was a large, very firm, and grossly nodular goitre which displaced the trachea and tilted the thyroid cartilage. It was slightly tender in places and moved on swallowing. There was no stridor and no bruit, and no clinical suggestion of retrosternal extension. He showed a trace of fine finger tremor, but no eye signs. There were a few small shotty glands in both posterior triangles but none elsewhere in the neck. His heart was of normal size, but there was a systolic ejection murmur at the apex. Nothing abnormal was found in the abdomen.

Investigations

On investigation for causes of the diarrhoea the stools showed only occasional traces of occult blood. Culture for salmonella and shigella was negative, and no cysts of *E. histolytica* were seen on eight tests. Sigmoidoscopy was normal to 15 cm. Barium enema showed extensive spasm in the sigmoid colon, with many diverticula in the sigmoid and transverse colon. These may have been the cause of the traces of occult blood. Barium meal and follow-through showed diverticula in the second and third parts of the duodenum. There was rapid transit and the rectum was reached in just over three hours. An *x*-ray film of the chest showed the heart and lungs to be normal. *X*-rays of spine showed ankylosing spondylitis with dorsal scoliosis. The intravenous pyelogram showed the kidneys and renal excretion to be normal. There were two diverticula in a trabeculated bladder. The urine contained no pus cells, but grew *Escherichia coli* on culture.

The chronic diarrhoea had caused relatively little metabolic change. The E.S.R. was 16 mm./hour. The haemoglobin was 13.6 g./100 ml., the M.C.H.C. 31.5, and the W.B.C. 7,000/cu. mm. with a normal differential count. The serum level of vitamin B_{12} was 520 mμg./ml. The urea was 23 mg./100 ml., and the sodium 137, potassium 3.6, chloride 96, and bicarbonate 29 mEq/l.

The total proteins were 7.1 g./100 ml., with albumin 3.8 and globulin 3.3. The α_2 and β fractions were elevated. The calcium was 4.9 and phosphate 1.8 mEq/l. The alkaline phosphatase was 12 King–Armstrong units. The xylose absorption was 4.1 g. after a 25 g. dose (normal 5–8).

Thyroid function tests showed the B.M.R. to be −5%. The 48-hour radioactive iodine output in urine was 63% (normal 35–70), with T index of 3.1 (normal 2.8–13); the 48-hour neck uptake was 19% (normal >20%); 48-hour plasma protein bound ^{131}I was 0.17% (normal up to 0.3). These tests suggested a mild degree of hypothyroidism.

Treatment

Treatment included a therapeutic trial of emetine for one week followed by diodoquine 650 mg. t.d.s., with emetine bismuth iodide 200 mg. daily. This produced no evident improvement. Symptomatic treatment with probanthine and codeine phosphate controlled the diarrhoea. He was discharged on 2 August 1963 with only mild improvement and an uncertain diagnosis.

He was seen again in outpatients in September 1963, when he continued to complain of general weakness and lassitude. There had been no further weight loss, and his bowels were fairly well controlled by codeine phosphate and chlorpromazine. For the first time he was beginning to find swallowing difficult. He returned to Cyprus in the following month.

He again visited Britain in 1965 and was seen in outpatients. His dysphagia was worse and he now tended to cough after swallowing fluids. On examination the goitre did not appear very different from the state two years before, but he now had a large firm supraclavicular gland on the right side. This was a new feature and was suspicious of malignancy. He was therefore readmitted for the third time on 10 August 1965 for biopsy.

Readmission

On examination his weight had dropped to 45 kg. The thyroid was now fixed on swallowing. There was no stridor and no bruit. There were distended veins over the goitre and the veins of his right arm were also distended. The vocal cords moved normally. The jugular venous pressure was not raised. The pulse was regular at 90–100, and the blood pressure was 120/70 mm. Hg. There were bilateral basal crepitations, and the liver edge could be felt 3 cm. below the costal margin.

The most important investigation was the lymph node biopsy. This showed medullary carcinoma of the thyroid gland with hyaline deposits.

X-ray of the chest showed an enlarging goitre mass extending through the thoracic inlet into the mediastinum. The spine showed severe ankylosing spondylitis, but *x*-ray of hands showed normal bone texture. The E.C.G. showed what were described as minimal non-specific abnormalities.

Culture of the urine produced a heavy growth of *E. coli* resistant to sulphonamide but sensitive to ampicillin.

Thyroid studies showed a neck uptake of 26% at 24 hours. The 48-hour urine excretion of ^{131}I was 59.8% with a T index of 4. A scan showed a particularly poor uptake on the right side of the gland.

The haemoglobin was 13.8 g./100 ml., the M.C.H.C. 31, and the W.B.C. 7,000 with normal differential. The blood urea was 12 mg./100 ml., the sodium 140, potassium 3.5, chloride 97, and bicarbonate 33 mEq/l. The serum bilirubin was 0.5 mg./100 ml., the thymol turbidity 3 units, zinc sulphate 7, and alkaline phosphatase 9 units. The acid phosphatase was 2.3 K.A. units with 0.3 tartrate labile. The lactic dehydrogenase was 135 units with 44% heat stable. The prothrombin time was 13 seconds. The serum calcium was 5.1 and phosphate 2.0 mEq/l.

The excretion of urinary 17-oxosteroids was 5.0 mg. daily and of 17-oxogenic steroids 5.5–9.5 mg. The urinary excretion of 5-hydroxy indole acetic acid was normal, and of vanillyl mandelic acid 4 µg./mg. of creatinine, a figure regarded as the upper limit of the normal range. Calcium excretion in the urine was 320 mg. daily and the output of indoles was 35 mg./24 hours (a normal figure). A glucose tolerance test showed a moderately diabetic curve with a high renal threshold. The stools still contained no pathogenic organisms and faecal fats were 4.4 g./24 hours.

Treatment

Treatment consisted in a course of deep *x*-ray therapy although the tumour was known to be rather insensitive. At first the dysphagia was aggravated, but later it improved. He was discharged on 15 October 1965.

By December 1965 the jugular vein was less obstructed. There was no further loss of weight, but the diarrhoea now needed larger doses of codeine for control. A trial course of neomycin gave no improvement in the diarrhoea. He again paid a visit to Cyprus.

His fourth and final admission to Hammersmith Hospital was on 29 March 1966. The malaise and weakness were more marked and the dysphagia was worse. He aspirated a lot of fluids. His speech was rather rambling, but he complained that something in his abdomen was making him short of breath. He was found to have pneumonia of the right lower and middle lobes. His liver was enlarged 7 cm. and had an irregular edge. The blood pressure was 95/60 mm. Hg. In spite of treatment with antibiotics he deteriorated rapidly and died two days after admission.

Clinical Diagnoses

(1) Medullary carcinoma of the thyroid.

(2) Secondaries in lymph glands and liver.

(3) Terminal right lobar pneumonia.

(4) Ankylosing spondylitis.

(5) Diverticulosis in duodenum, colon, bladder, and pharynx.

(6) Mild diabetes mellitus.

Post-mortem Findings

Dr. E. D. WILLIAMS: The necropsy on this thin elderly male was carried out 12 hours after death. No mucocutaneous tumours were present.

The most interesting findings were in the endocrine system. The right lobe of the *thyroid* (Fig. 1) was uniformly enlarged to form a smooth solid mass, 8×4.5×4.5 cm., with a variegated red-brown cut surface. Microscopy showed that this was a medullary carcinoma (Fig. 2), largely the spindle cell variant, with abundant amyloid deposition and focal calcification within amyloid (Fig. 3). In some areas the tumour was more anaplastic, forming ill-defined round masses of tumour cells, with many vacuoles but little or no amyloid; in these areas it resembled the tumour found in the cervical lymph node biopsy. Secondary deposits of medullary carcinoma were found in the cervical lymph nodes, a matted mass of nodes in the upper mediastinum, the pleura, throughout the grossly enlarged liver, and in the vertebral marrow. The left lobe of the thyroid was small, with a single small white nodule (0.4 cm. diameter) (Fig. 4) which proved to be a medullary carcinoma with abundant amyloid. In view of the scarcity of amyloid in the secondary deposits elsewhere, the solitary nature of this nodule, and the previously reported instances of bilateral medullary carcinoma, it was considered that this was a second primary tumour. Two normal parathyroids were found. The pancreas was rather autolysed, but the islets appeared normal. Both adrenals were enlarged (Fig. 5); the left (14 g.) contained a central soft rounded brown tumour (2.5 cm. diameter). The right adrenal (9 g.) showed a central collapsed partly cystic tumour (1.5×1 cm.). Both on microscopy were benign phaeochromocytomas (Fig 6), the right one being largely degenerate but also containing a small secondary deposit of medullary carcinoma.

In the *alimentary tract* the duodenal and colonic diverticula were confirmed; the villi had lost their epithelium but were not flattened. The intestinal nerve plexuses were normal.

The only significant abnormal finding in the urogenital tract was in the bladder. This showed two diverticula, and on section the muscle in places formed whorls and nodules in an abnormal growth pattern.

In the *respiratory tract* the trachea was deviated to the left, and both lungs were moderately overweight. Widespread large and small pulmonary emboli were present, with scattered infarcts, but no significant infection was found.

The *skeletal system* showed bony ankylosis of cervical dorsal and lumbar vertebrae.

There were no relevant findings in the *cardiovascular system,* nor, apart from secondary carcinoma, in the *reticuloendothelial system.* The *central nervous system* could not be examined, because necropsy permission was limited.

Pathologist's Diagnosis

(1) Bilateral primary medullary carcinoma of thyroid, with widespread secondary deposits.

(2) Bilateral phaeochromocytomas of adrenals.

(3) Diverticula of intestinal tract and bladder.

(4) Massive pulmonary emboli.

(5) Ankylosing spondylitis.

Discussion

Dr. COPE: This is a fascinating case. So far as I can gather the medullary carcinoma of the thyroid is a form which has been recognized only in the last 10 years. We did not diagnose it, except in so far as we called for a biopsy. Dr. Williams diagnosed it, and he is our expert on this disorder; we hope

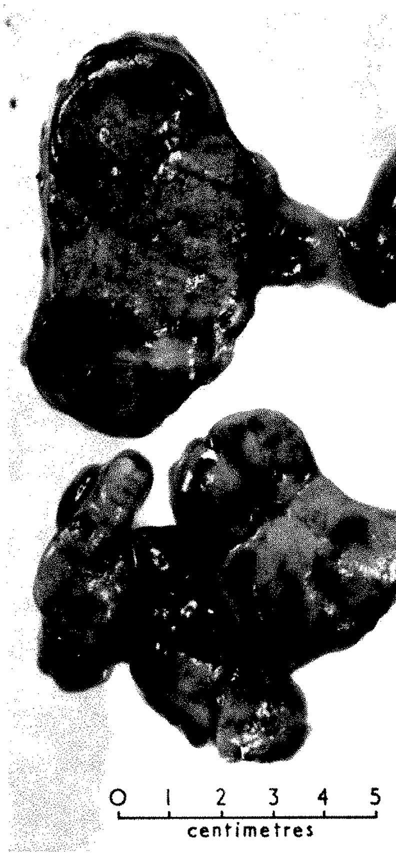

FIG. 1

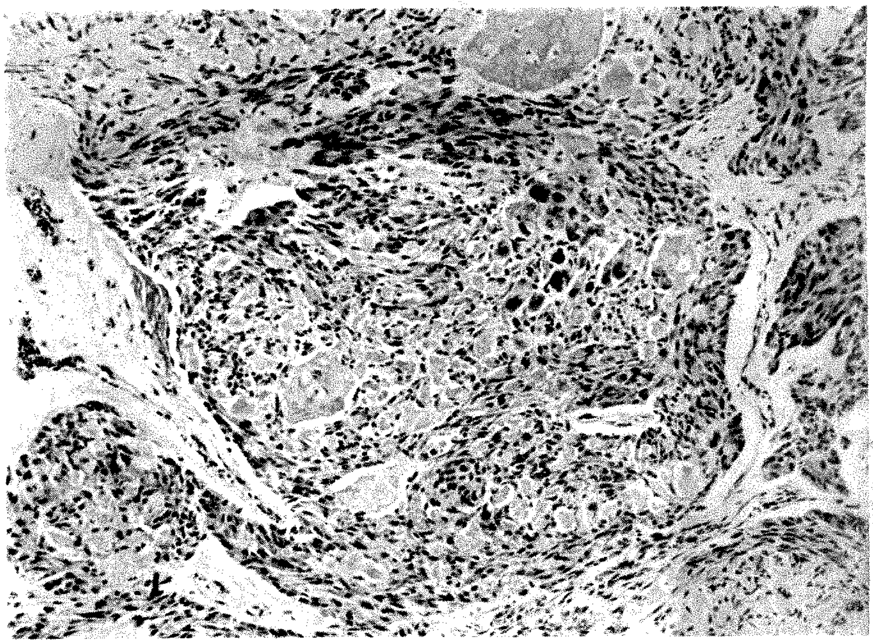

FIG. 2

FIG. 1.—Thyroid, with right lobe transected to show a massive well-circumscribed tumour, and mediastinal lymph nodes also replaced by tumour.

FIG. 2.—Medullary carcinoma of right lobe of thyroid. Note the abundant amyloid deposition. (H. and E. ×105.)

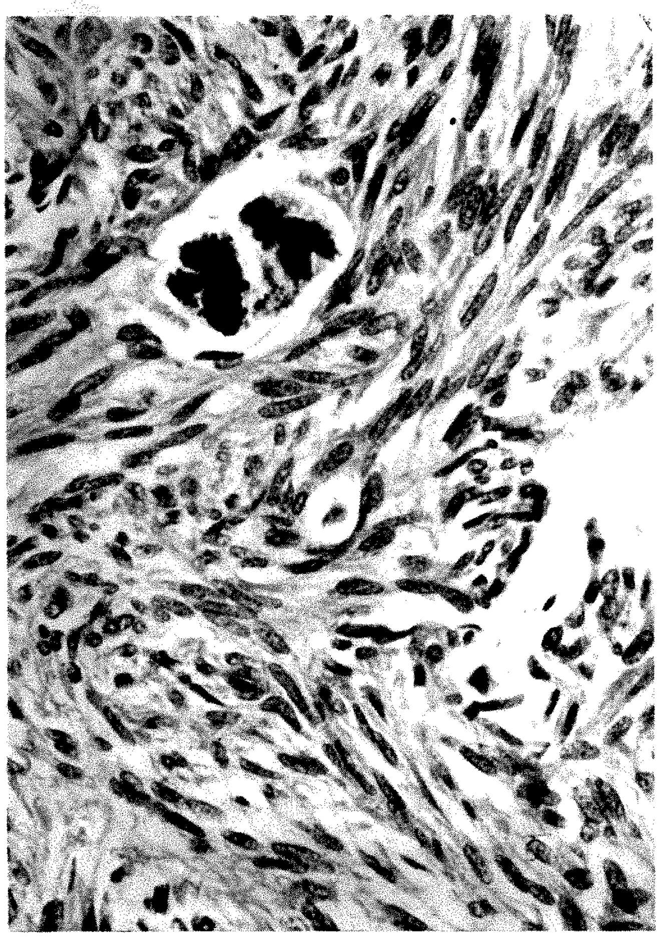

FIG. 3.—High-power view of the same tumour. The dark granular material is calcification within a deposit of amyloid. The carcinoma shows predominantly a spindle-cell pattern. (H. and E. ×440.)

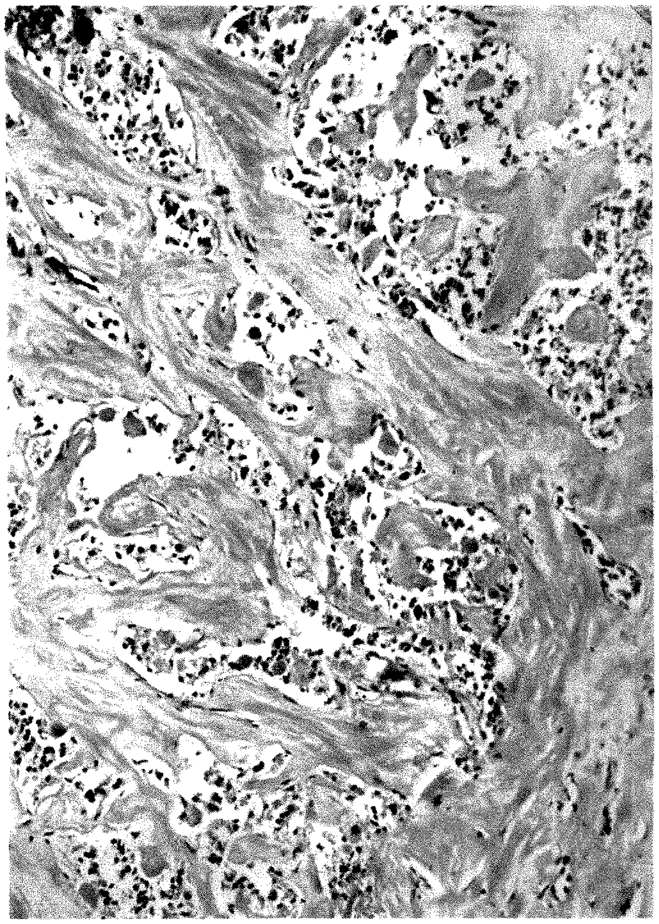

FIG. 4.—Tumour from left lobe of thyroid. This is also a medullary carcinoma with abundant stromal amyloid, and is probably a second primary tumour. (H. and E. ×110.)

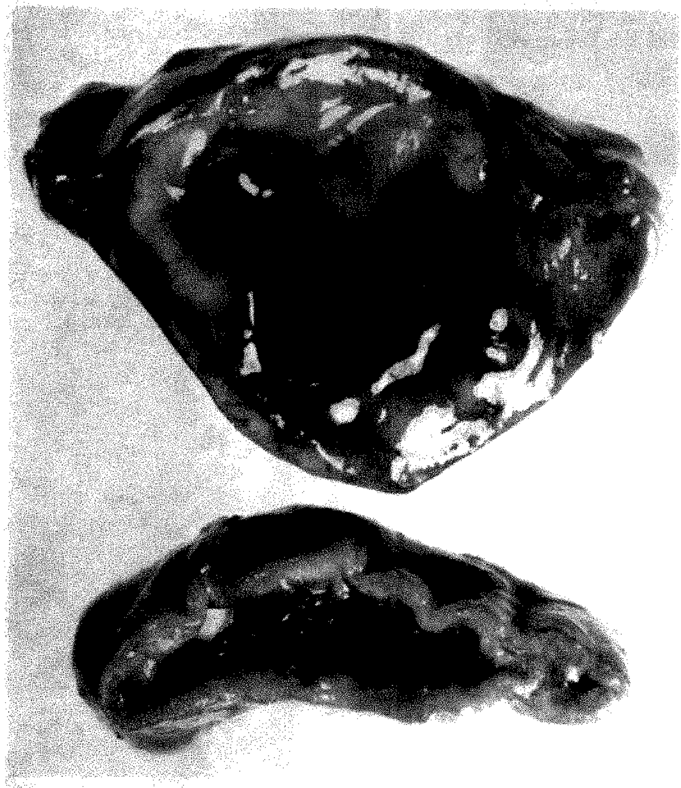

FIG. 5.—Both adrenals bisected to show bilateral phaeochromocytomas. (×3.3.)

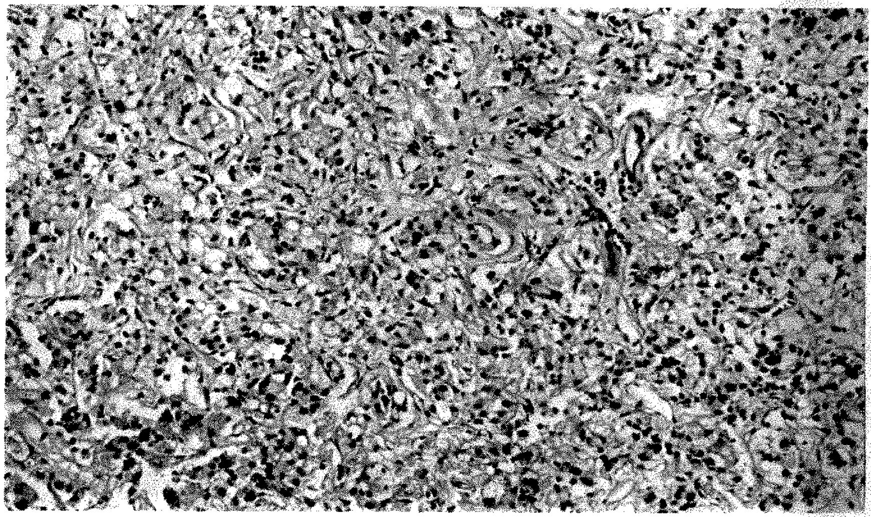

FIG. 6.—Phaeochromocytoma of left adrenal. The tumour shows the typical packeted arrangement of regular large cells with abundant granular cytoplasm. (H and E. ×105.)

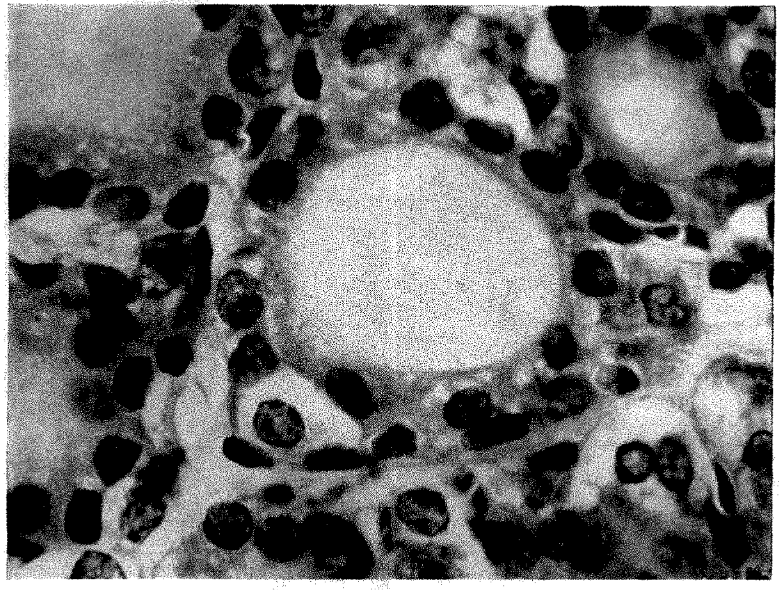

FIG. 7.—High-power view of a thyroid from an aged rat. The parafollicular cell is seen as a cell with pale cytoplasm separated from the colloid by the darker cytoplasm of the follicular cells. (H. and E. ×910.)

to hear a lot more about it from him in due course. We diagnosed the presence of malignancy clinically by two of the classical criteria, increasing dysphagia, and the appearance of a lymph node which was an obvious metastasis.

Cause of Diarrhoea

We did not, however, realize there was any link between this medullary carcinoma and the symptom of persistent diarrhoea. The association between medullary carcinoma and persistent diarrhoea is, I believe, a discovery made by Dr. Williams himself. Certainly we found no other cause for it; I do not think for a minute the diverticula were an adequate cause—there was no infection, and there was very rarely any occult blood. There was no other local cause, and I think Dr. Williams must be perfectly right in suggesting that there was a humoral cause for this intestinal hurry, which the patient undoubtedly had right through to the colon. At no time did we as clinicians consider a phaeochromocytoma, and even in retrospect there was no evidence of it. He never had any cardiovascular episodes, any episodes of paraesthesia, of pallor, of headaches, of paroxysms of hypertension, and never was any raised blood pressure recorded, so far as I am aware. The vanillyl mandelic acid test, which was done after we knew the diagnosis at the suggestion of Dr. Williams, was at the upper limit of normal, but not high enough to give us any real clue. Some of you may have seen the very opportune paper in the *British Medical Journal*[1] about this particular association of medullary carcinoma with phaeochromocytomas and its familial incidence. It is interesting that this particular patient had a mother who, when we last heard, was still alive at the age of 89 but had an enlarged thyroid and had complained of diarrhoea for many years of her life. Obviously it was not a death-dealing disorder in her case. The wife and three brothers were alive and they were all well. The patient's father had died at the age of 61 with what was described as congestive cardiac failure. One can only speculate whether that was in any way related to a phaeochromocytoma. We do not even know if he had a goitre. There are many points of interest here, the thyroid aspects, the reasons for the diarrhoea, and the question of diverticula as a possible alternative cause for the diarrhoea.

Diarrhoea and Thyroid Tumours

Dr. Williams: The relationship between the thyroid and the diarrhoea is based on a study of a large number of cases which I collected together with Professor Doniach and Dr. Brown from various London hospitals; we collected them mainly to look at the pathology of this type of tumour. In going through the records it became apparent that a surprisingly large number of them showed diarrhoea. The diarrhoea correlated with the extent of the tumour, in that very few patients with tumour localized to the neck had diarrhoea, and a very high proportion of patients with widespread tumour had diarrhoea. Also, in four patients there was evidence that when the tumour was resected the diarrhoea improved, in two of them to recur again when the widespread tumour recurred. Putting these observations together it seems likely that there was a humoral factor linking the tumour with the diarrhoea. The other points which made this a likely possibility are the resemblance that this tumour bears to certain other hormone-secreting tumours like carcinoids. This resemblance is both histological and histogenetic, as there is evidence to suggest that this tumour does not arise from the ordinary follicular cells of the thyroid but from a second type of thyroid cell, the parafollicular cell. This cell has a number of different possible functions, among them the production of calcitonin; in the sheep this cell has been shown to contain 5-hydroxytryptamine (5 H.T.).

We therefore have a tumour of a cell which is potentially capable of making 5 H.T., and which is likely to have a humoral function unrelated to thyroxin. The nature of the humoral factor leading to diarrhoea is another point. Despite the fact that this tumour may occasionally make 5 H.T., this does not seem to be the cause of the diarrhoea. Slightly increased 5-hydroxyindolacetic acid excretion was found in two out of the seven cases where we've had a chance of testing urine. In one case we found a raised level of kallikrein in the tumour. Kallikrein is the enzyme secreted by carcinoids which releases small chain polypeptides from their precursor kininogen, an alpha-2 globulin. We have since failed to find kallikrein in several other tumours, so I think there must be some other factor, and we are now investigating various other possibilities.

Professor C. Booth: What about calcitonin? If this tumour is derived from the cells which secrete calcitonin, why doesn't this tumour secrete calcitonin?

Function of Thyroid Cells

Dr. I. McIntyre: May I comment here? The thyroid is really two separate endocrine glands: the A cells, secreting the iodothyronins; and the C cells, which normally secrete calcitonin. This is reasonably well established now, both biochemically and immunochemically. Now, I would like to ask Dr. Williams whether he thinks this tumour arises from a third cell type within the thyroid, or whether he thinks it arises from the C cells. I think it's better to use the term "C cells" for the calcitonin-producing cells, because they cannot be described simply as parafollicular, as their position varies from species to species.

Dr. Williams: That question is best answered by reference to a photomicrograph of thyroid tissue (Fig. 7). This is a high-power view of a rat thyroid gland. It shows the follicles full of colloid and lined by follicular cells. In the centre is a second type of cell with a clear cytoplasm. The follicular cells link together to separate this clear cell from the colloid, and I think that should immediately make one suspect that its function is unrelated to the production of colloid or thyroxin. In the sheep these cells have been shown to contain 5 H.T., while in other animals the cells with a similar morphological position have been shown to contain calcitonin. Now, to answer Dr. McIntyre's comment. We can compare the thyroid to the pancreas. In some species of fish the islet cells line the ducts between the duct epithelium and the basement membrane, whereas in mammals they form the distinct cell groups known as the islets of Langerhans. Similarly in some species, for example the rat, the second type of thyroid epithelial cells lie between the follicular cell and the basement membrane, while in others, particularly the dog, they form "thyroid islets" of solid cells lying between the follicles. These cells may have a variety of different functions. Two of the functions that are known are that in some animals they can make 5 H.T., and that in others some at least of the cells can make calcitonin and therefore can be known as C cells. A C cell is defined in terms of production of calcitonin. Maybe there are several different types of epithelial cell in the thyroid apart from the follicular cell. I don't think at present we really have enough evidence to answer the question of whether there is a cell type for each hormone produced.

Dr. I. Gilliland: Are they necessarily homogenous cells, these "islets of Williams"? Even morphologically they differ from one place to another.

Dr. Williams: I prefer to let Professor Pearse answer that question.

Hypercalcitonaemia

Dr. Cope: May I ask Dr. McIntyre if it is yet known what the symptoms are of hypercalcitonaemia, and whether we may not perhaps be missing the world's first calcitonin-producing tumour?

Dr. McINTYRE: Unfortunately we can't measure calcitonin in serum. I think one would predict that the symptoms would be impaired resorption of bone and would be rather similar to the kind of picture which one might see in marble bone disease. Dr. Doyle and Dr. Foster showed that if calcitonin is given to animals for long periods the equivalent of "rugger jersey" spine is produced. So the long-continued over-secretion of calcitonin might produce impaired resorption of bone with "rugger jersey" spine and osteopetrosis. With a short history like this I don't think one would be able to detect bony changes. We need a means of measuring calcitonin in the blood.

Professor BOOTH: You don't think the calcification that Dr. Williams showed us in the amyloid tissue or in the ligaments in relation to the ankylosing spondylitis could have anything to do with this?

Dr. McINTYRE: I think it could, Professor Booth, but we just don't know.

Dr. WILLIAMS: If there was calcitonin production by the tumour would one not expect parathyroid hyperplasia secondary to this? I have seen one case of medullary carcinoma which at necropsy had unexplained parathyroid hyperplasia.

Thyroid C Cells

Professor BOOTH: Professor Pearse, have you anything further to add on the C cells?

Professor A. G. E. PEARSE: They have a number of characteristics, over a wide variety of species or genera, and in no single case are all the characteristics present. The electron-microscopic appearance is the one which is most uniform, and they can be seen very easily in electron micrographs of rat thyroid. The problem is to find C cells in the human thyroid. The classical method of showing them is by the Cajal silver stain which was used by Nonidez in 1931. The cells were first seen by E. C. Baber, who was an ear, nose, and throat surgeon in Brighton. He described them in 1877, and they should be called Baber cells if you use a name at all. A second method of showing them works in every animal in which I have tried it, but I have not tried it in man. This is because it is necessary to inject an amine-precursor, such as 5-hydroxytryptophan (5 H.T.P.). This is taken up and converted by the C cells to 5 H.T. Normally the cells don't manufacture 5 H.T., so I must take exception to Dr. Williams's statement on that point. There is no evidence that they manufacture it, only that they will if you give them a chance. C cells which have taken up 5 H.T.P. and converted it to 5 H.T. can be shown by the so-called fluorescent amine technique. One cannot ethically give a human being a large dose of 5 H.T.P. in order to show the C cells. However, one can do it with radioactive 5-H.T.P.; an easier way of doing it, perhaps. Only in the sheep and perhaps the horse are the C cells known to have 5 H.T. in them normally. There is one further method of showing them up. In many animals they contain high levels of α-glycerophosphate dehydrogenase. With a fluorescent antibody technique, using anti-pig calcitonin, the C cells of the pig and also of the dog show the fluorescent label. This indicates that calcitonin is stored in the C cells (C for calcitonin).

Professor BOOTH: Are they specific medullary cells, or do all medullary cells show this?

Professor PEARSE: We don't use this term except in the case of the human carcinoma. There are specifically interfollicular cells, but in most animals, as you've heard, they are part of the follicle wall. Not every cell that is interfollicular is a C cell; there are other cell types between the follicles, some of which might form a tumour.

Dr. COPE: Does a medullary carcinoma take up this particular antibody?

Professor PEARSE: We have never tried it—we haven't got enough to waste on human cases. In the normal human thyroid it is very difficult to find any C cells, even with the α-glycerophosphate dehydrogenase technique. I believe, although the article in the *B.M.J.*[1] said that these cells could not be detected in the human thyroid, that, in fact, they can be.

Professor BOOTH: What we've got, then, are some cells which may produce calcitonin, and Dr. Williams believes these cells are the origin of this tumour. We've now got to ask what the relation is between this tumour and the tumour of the adrenal.

Relationship to Adrenal Tumour

Dr. WILLIAMS: Perhaps I should comment on that. Firstly, there is no doubt there is a relationship. I now know of 40 cases, either seen by myself or published, of carcinoma of the thyroid and phaeochromocytoma. In 30 of these the tumour of the thyroid is a medullary carcinoma, and in three of the others the description leaves very little doubt that it was a medullary carcinoma—that leaves only seven, and none of those seven was described as clearly a papillary carcinoma of the thyroid, which is the commonest type. So I think there is no doubt that there is a specific relationship between the two. Secondly, the phaeochromocytomas are commonly bilateral, and commonly the whole syndrome is familial, as the article by Ljungberg and his colleagues[1] illustrates. Now, one of the explanations put forward is inheritance of a pleotropic gene of incomplete penetrance—which I think I am right in saying is an explanation that will explain almost anything. I am not saying it's not true, but I don't see how one could possibly prove it. The thyroid carcinoma also seems on occasions to be bilateral, so I suppose that the genetic explanation is the most likely one. Why tumours of thyroid and adrenal medulla should occur together is much more difficult to explain. The only analogy is the multiple endocrine adenoma syndrome, in which tumours of pituitary, parathyroid, pancreatic islet, and adrenal cortex occur. This certainly is familial, and maybe there is a growth factor that controls all these endocrines. If that is the case one has to postulate a second growth factor that controls the parafollicular cells in the thyroid, the adrenal medulla, and possibly also controls the growth of some of the autonomic nervous system. In a small proportion of cases with carcinoma of the thyroid and phaeochromocytoma a wide variety of autonomic abnormalities is also found: ganglioneuromatosis of the whole intestinal tract, also described in the bladder and the bronchus, and small mucosal neuromas of the eyelids, lips, and tongue. It is possible that there is a single factor controlling the growth of all these different tissues. We know now that there is a nerve growth factor, described by Levi Montalcini, that controls the growth of some nerves, and she has also found a skin growth factor. Thus it may be that there is an endocrine growth factor which is responsible either for the typical multiple endocrine adenoma syndrome or for this second type of syndrome with medullary carcinoma, phaeochromocytoma, and sometimes other neural abnormalities.

Professor BOOTH: Can we just get one thing clear—these are not overlapping syndromes—you're using the polyglandular one as a comparison.

Dr. WILLIAMS: I'm using the multiple endocrine adenoma syndrome as a comparison. To the best of my knowledge even in the more comprehensive studies of many families with the multiple endocrine adenoma syndrome phaeochromocytoma has never been recorded. To be absolutely honest even if confusing, there is an overlap in that parathyroid adenoma has been described in both. Four cases of medullary carcinoma of the thyroid and parathyroid adenoma have been recorded.

Clinical Course

Dr. COPE: I was just going to ask Dr. Williams whether in the light of his survey of these cases, and his peculiar knowledge of them, he could comment on the clinical course of these goitres. They are surprisingly slow growing for thyroid carcinomas generally, are they not?

Dr. WILLIAMS: There is a very great variability in prognosis. With some patients the survival is only a year or two, while the longest survivor that we've had in our series was 21 years. This patient was a man who died at the age of 42 who had had a thyroidectomy when he was 21. However, he had had a goitre before that, according to various reports either since birth or at least since the age of 8. With a tumour of the thyroid which is originating from a different cell type, it's not so surprising to find a spectrum of malignancy within that group of tumours—either relatively benign ones or relatively malignant ones.

Dr. GILLILAND: This must have been a most unusual man—there is a reference to his "having something in his abdomen makes him short of breath"—are these not hypertensive attacks he's having, or high blood pressure?

Dr. COPE: No, the blood pressure was never raised—I didn't see the point in giving innumerable figures. This "something in his abdomen making him short of breath" was in the last two or three days only. But he had a very large liver and he had two phaeochromocytomas. Maybe he knew he had one or the other.

Dr. GILLILAND: I am showing a case quite shortly—with Professor Welbourne—who had paroxysms only in the evening; this was missed for two years while she was in hospital because the attacks were never noticed during the day.

Dr. WILLIAMS: The phaeochromocytoma does not have to function, does it? A proportion of these patients can presumably go all through life and never have any symptoms at all.

Dr. GILLILAND: This patient, however, had a mild diabetes.

Professor J. GOODWIN: The diabetes and the diarrhoea might have been due to the phaeochromocytoma, might they not? I don't know quite why you attribute the diarrhoea necessarily to the carcinoma.

Dr. WILLIAMS: Because in a number of cases of diarrhoea and medullary carcinoma no phaeochromocytoma was found at necropsy. Also because the diarrhoea improved in some cases after resection of medullary carcinoma. I agree that phaeochromocytoma may occasionally present with extreme diarrhoea, but the link there is also humoral and unexplained so far as I'm concerned.

Professor GOODWIN: I think the "something in his abdomen making him short of breath" was pulmonary embolism.

We are grateful to Professor J. P. Shillingford and Dr. E. D. Williams for assistance in preparing this report, and to Mr. W. Brackenbury for the photomicrographs.

NEW APPLIANCES

New Urinary Diversion Appliance

Mr. H. B. ECKSTEIN, consultant surgeon, Queen Mary's Hospital for Children, Carshalton, Surrey, writes: With the rapidly increasing number of children surviving with myelomeningocele and hydrocephalus, the problem of urinary incontinence, and therefore urinary diversion, in childhood is becoming more important. Though a wide range of appliances are available for these patients, there is at present no completely satisfactory appliance.

The important features of an appliance for a urinary diversion either by an ileal conduit or by cutaneous ureterostomy are that it should be easy to apply and be easily cleanable and sterilizable; but since rubber bags cannot be cleaned properly and certainly cannot be sterilized adequately they should be either disposable or semi-disposable. It is impossible to clean and sterilize the outlet tap of the bag, and this should therefore not come in contact with the urine. The bag should contain a one-way valve to prevent reflux of urine on to and into the stoma when the patient is lying down.

With these basic conceptions in mind we have designed an appliance with plastic bags fitted with a slit valve and an external tap which will fulfil these criteria. We have tried these bags out on a number of children with considerable success. This appliance is manufactured by Eschmann Bros. & Walsh Ltd. and is now available through all appliance suppliers. While it may not be suitable for every single child, it is certainly an improvement on previously available models. The appliance is illustrated in Figs. 1-3 and is supplied initially in a basic set with replacement bags and flanges which are prescribable on E.C.10 forms.

It is marketed as the "Carshalton Appliance," and fitting instructions are enclosed with each set. Encrustation of the stoma, a common complication of uretero-ileostomies in children, has been virtually eliminated by the use of a disposable bag.

I should like to express my thanks to my colleagues for their helpful criticisms and advice and to Mr. Peter Steer, of Eschmann Bros., for his patience and help in making the many modifications to produce the final product.

HOSPITAL TOPICS

Organization of a Coronary Care Unit in a General Hospital

B. L. PENTECOST,* M.D., M.R.C.P.; N. MAYNE,† M.D., M.R.C.P.; PATRICIA LAMB,‡ S.R.N.

Brit. med. J., 1967, 3, 298–300

The current interest in intensive care units for patients with myocardial infarction centres on the fact that many die not of extensive myocardial damage but of potentially reversible arrhythmias. In recent years techniques of cardiac resuscitation have advanced considerably. Most nursing and medical staff are familiar with external cardiac massage and artificial ventilation, and many hospitals are in possession of some form of external defibrillator. The purpose of an intensive care area is simply to bring all patients at risk together in an adequately equipped ward unit and to provide the optimum facilities for early detection and treatment of complications after myocardial infarction. If the coronary care unit is to make any impact on the national mortality from myocardial infarction it must be adapted to the needs, and means, of the busy general hospital. The requirements of such a unit differ from those of an ordinary intensive care unit and do not appear to have been discussed in relation to the district hospital.

The General Hospital, Birmingham, admits approximately 250 patients a year with acute myocardial infarction. The coronary care unit must, however, be prepared to admit at least 300 patients a year, because many are admitted on suspicion of having sustained myocardial infarction and the diagnosis is subsequently not proved. A coronary care unit was opened in October 1966, and this paper discusses some of the problems of organizing and equipping such a unit in a general hospital.

Site and Structure

It is important for the coronary care unit to be as self-contained as possible; an independent unit in terms of both staff and any ancillary services which may be required urgently—for example, radiological screening and acid–base determinations. To nurse patients with myocardial infarction within an ordinary intensive care unit is unsatisfactory. They require a calm atmosphere and reassurance and would suffer considerable anxiety in such surroundings. However, it would seem that there may be a great advantage, in terms of sharing equipment and skilled staff, in the juxtaposition of these two forms of unit. We decided against partitioning off a section of a general ward as a coronary care unit. It is difficult to maintain constant vigilance on one group of patients in a busy ward, and, though complex electronic monitoring equipment may to some extent replace the nurse's powers of observation, warning signals are of no avail in the absence of staff immediately free to render assistance. In addition, we have found that when patients are singled out for close observation in a general ward, particularly when attached to an oscilloscope, they feel insecure and apprehensive. Conversely, in a small ward where such techniques of observation are seen to be applied universally the individual does not feel that he is particularly at risk.

A ward day-room was finally selected. It measures 560 sq. ft. (52 sq. m.) and accommodates five beds arranged radially. A larger area would confer greater freedom of access to the beds, particularly after an arrest when several staff and bulky equipment surround the patient, and would allow construction of cubicles with rigid partitions. There is, however, then some risk of losing the intimate contact with the patient which a small open ward confers, and monitoring equipment needs to be more elaborate. At present beds can be partitioned off with curtains, and one recessed area is set aside primarily as a resuscitative area, though resuscitation may be carried out on any of the five beds.

Sphygmomanometers are wall-mounted behind each bed beside a notice-board for the display of blood pressure charts and other clinical data. Oxygen is piped to the ward from the main hospital supply. Piped suction is not available and a portable sucker is stored in the unit. A liberal supply of power points is vital in view of the amount of electrically powered equipment. Some thought needs to be given to the placing of power points and cable lengths in order that the equipment is available to all parts of the unit.

The nursing station is simply a desk where notes may be written and nursing intructions given. There is no sister's office, so that the nurses are constantly in the ward. At night a nurse sitting at the desk may see all five patients and their attendant oscilloscopes.

The position of the coronary care unit within the hospital is of considerable practical importance. The unit requires to be as near as possible to its main source of patients—the casualty department—and to its main area of patient discharge, the male general medical wards. The General Hospital coronary care unit is well placed between the two principal male medical wards but at some distance from the casualty department. This is a disadvantage, for we play a smaller part than we would like in the initial resuscitation of the patient with a complicated myocardial infarction on his arrival in that department. In addition, the risk of cardiac arrest occurring in transit from casualty to the coronary care unit is not negligible. However, our current site facilitates good working relations with the wards to which we discharge patients and from which they occasionally return.

Apparatus and Equipment

Beds.—It is clearly desirable to avoid resuscitation on the floor of such a small ward unit. We have therefore adapted the ordinary hospital beds to allow external cardiac massage to be effectively performed without moving the patient to the floor.

---

* Consultant Physician, the General Hospital, Birmingham.
† Senior Medical Registrar, the General Hospital, Birmingham.
‡ Sister in charge of the Coronary Unit, the General Hospital, Birmingham

Beds are fitted with braked castors for stability during resuscitation and ½-in. (1.3-cm.) boards are permanently placed across the upper half of the bed frame. When propped upright with pillows the patient is unaware of the underlying boards. A 3-in. (7.5-cm.) polyethylene mattress is normally comfortable for the patients, but allows external cardiac massage to be performed effectively. The head of each bed has been sawn through at the uprights above the level of the spring frame and an obturator has been inserted into both upper sections. The head of the bed is then easily detached to allow tracheal intubation.

When transvenous cardiac pacemaking is indicated this procedure is carried out within the unit. One bed has been further adapted for this purpose. In order to permit the introduction of an *x*-ray source beneath the bed the legs have been lengthened by 3 in. (7.5 cm.). All metal springs have been removed and a 2-in. (5-cm.) radiotranslucent polyethylene mattress is supported by ½ in. (1.3 cm.) of plywood mounted on the bed frame. Satisfactory radiological screening may be obtained in this way and the bed is comfortable enough to lie on. The position of the pacemaker catheter tip may be checked if necessary. The walls, floor, and ceiling of the unit are sufficiently dense to eliminate the need for further protective screening around the unit for the amount of radiation involved. The swing doors leading to the coronary care unit have been lined with 1 mm. of lead.

Display and Monitoring Equipment

A wide range of electronic equipment is currently available to any type of intensive care unit. Some of this seems to be unnecessarily complex for our purpose—for example, monitoring body temperature and respiratory rate is of little value in the coronary care unit. We have come to use the oscilloscope simply as a display apparatus, seldom using the monitoring and alarm systems. This is possible in a fairly small unit when nurses have been taught some elementary electrocardiography. Initially the nursing staff were asked to perform routine tasks—for example, counting the frequency of ventricular extrasystoles for one minute in the hour. This in itself was of little value but served to draw attention to the oscilloscope. Interest was further stimulated by a collection of common electrocardiographic abnormalities, including infarction patterns and arrhythmias. As a result the nursing staff have become extremely skilled in the detection of arrhythmias. The provision of a simple single-channel recorder enables the nurse to make a permanent recording of any arrhythmia direct from the oscilloscope.

Most warning systems are activated by a change in heart rate outside a preset range. A nurse may detect additional abnormalities—for example, the early stages of atrioventricular block or an alteration in frequency or form of ventricular extrasystoles. In addition, as indicated by Thomas (1967), mechanical cardiac arrest may occur in the absence of change in the electrocardiogram so that direct observation of the patient remains of primary importance.

Patients do not resent the physical attachment to an oscilloscope provided that it does not entail conventional leads, which not only hamper the patient's movement but make any nursing procedure difficult. We have elected to place the limb leads on the left upper arm with a single exploring electrode on the anterior chest wall, thus leaving the right arm and both legs free. Other similar electrode arrangements have been described (Fluck *et al.*, 1967). Some form of small lightweight adhesive electrodes are best for this purpose.

The floor is kept as free as possible from unnecessary equipment, and for this reason we arrange oscilloscopes on a shelf behind the patient or on a small bedside stand. Probably wall rails for all equipment provide the ideal solution.

Apparatus is available for measurement and recording of intravascular pressures and cardiac output, but this is probably not necessary for practical purposes. The central venous pressure can always be measured by a simple water manometer via a polyethylene catheter advanced from the arm into the right atrium.

Radiological and Resuscitative Equipment

Although routine diagnostic radiology may be performed in the usual way it is advisable for the coronary care unit to be independent of the radiology department in the matter of screening. The rapid introduction of a cardiac pacemaker catheter into the heart by the transvenous route may be one of the most valuable contributions to the care of the patient. It is preferable to undertake this task in the unit and to avoid removal to another part of the hospital building which involves the patient in additional risk and delay. A portable image intensifier with closed-circuit television enables this to be performed within the coronary care unit and avoids the necessity of darkening the whole unit while screening.

The coronary care unit is equipped with a D.C. defibrillator and adequate apparatus for artificial ventilation—for example, oropharyngeal airways, self-inflating ventilating bag, laryngoscope with a wide range of cuffed endotracheal tubes, etc. The emergency drug cupboard is portable and contains all necessary resuscitative drugs, including 100-ml. infusion bottles of 8.6% sodium bicarbonate which are freshly dispensed by the pharmaceutical laboratory. Each piece of equipment has its own set position in the unit; this is important for speed of access in an emergency. An annexe of the unit contains blood-gas analysis apparatus for the rapid determination of arterial *p*H during resuscitation.

Electrical Hazards

The accumulation of electrical equipment poses certain hazards to the patient. Voltage build-up may easily occur on many forms of equipment, including cardiac monitoring apparatus. Normally it is unlikely that serious harm will result, since the high resistance of the patient's own tissues will prevent flow of current through the myocardium. However, the patient with a low resistance conduction line to the heart—for example, an indwelling cardiac pacemaker catheter or an intracardiac E.C.G. lead—is at considerable risk, as only a slight current (around 200 microamps) requires to flow through the myocardium to produce ventricular fibrillation. Though the pacemaker unit is screened from the A.C. mains, fatal voltage may still be applied to the myocardium unless all bare metal electrode attachments of the catheter are carefully insulated. All apparatus should be carefully and regularly checked for voltage build-up by a technique similar to that described by Whalen and Starmer (1967).

Staff

The coronary care unit provides a hospital service, and all patients suspected of having suffered a myocardial infarction are admitted to the unit under the overall care of their own consultant physician. One consultant physician and a senior registrar advise on the management of all patients within the coronary care unit, but the registrar and house-physician admitting the patient continue to look after him throughout his stay in hospital. These arrangements have the advantage of offering all junior staff experience in this work, and of providing a continuity of patient-care throughout the admission. The physician and senior registrar permanently attached to the coronary care unit provide uniformity of patient-care.

The nursing staff—one sister and seven staff nurses—are employed entirely in the coronary care unit. The observations required of the nurses and the speed with which they must reach decisions and act upon them make frequent change of nurses quite impracticable. Student nurses not infrequently spend short periods of time within the unit to gain some insight into its techniques and work, but an experienced member of the staff is always present. The nursing staff are often able to guide relatively inexperienced doctors in the identification and management of certain arrhythmias. In addition they explain to the patient and his relatives the nature and purpose of the equipment with which he comes into contact.

Duration of Patient's Admission

Most patients, male and female, spend three to four days in the unit, and, if they pursue an uncomplicated course, are then transferred to the general ward. Patients with serious arrhythmias, hypotension, or cardiac failure remain longer. Since it is our policy in the treatment of complete heart block to leave a catheter pacemaker in situ for three weeks in spite of a return to sinus rhythm, these patients remain with us for the whole of this period.

We encourage only short visits from close relatives for the first few days. The kitchen of the general ward to which the coronary care unit is attached supplies all meals. As the diet is predominantly fluid and extremely light for the first three days after admission the kitchen facilities required are not demanding.

Practical Experience

One is entitled to ask what sort of return is likely to be seen for this considerable outlay in money and staff. The following is not intended to be a detailed analysis of our work but a brief summary which gives some idea of what may be expected.

In the first six months of full operation, 144 patients were admitted to the unit and in all but three the diagnosis on admission was thought to be acute myocardial infarction. In 116 of them the diagnosis was eventually confirmed by electrocardiographic and biochemical evidence. There were 23 deaths, but without knowing more about individual patients, in particular the delay before admission to the coronary care unit, this figure has little significance. Of more interest is the fact that resuscitation has been required for ventricular fibrillation on 10 patients in the unit. One patient had two episodes of ventricular fibrillation and another had four. Five of these patients survived to be discharged from hospital. Two elderly patients had cardiac arrest during the journey from casualty and resuscitation was ineffective. This reflects on the importance of placing the coronary care unit within the vicinity of the casualty department. Of seven patients with complete heart block four required transvenous pacing for very slow heart rates with either syncope or cardiac failure. Of these seven patients six have left hospital. Two patients with ventricular tachycardia have required cardioversion under general anaesthesia; both survived.

There may be several other benefits to the patient in the form of early diagnosis and treatment of heart failure, hypotension, and some of the less immediately serious arrhythmias, and perhaps even from being nursed in a quiet area of the hospital with adequate analgesia. The patients almost without exception appear to be reassured by the constant presence of nursing staff and the calm atmosphere of the unit. The effect, however, of such factors on the morbidity and mortality of myocardial infarction is extremely difficult to assess.

British Medical Association

Annual Scientific Meeting, Bristol, 10–14 July

The first part of the report of the Scientific Meeting appeared in last week's B.M.J. (22 July, p. 227). The report is concluded below.

Plenary Session on Recreation

Thursday, 13 July

The plenary session on recreation was chaired by the MARQUESS OF EXETER, the former Olympic hurdler. He was introduced by Mr. ROBERT V. COOKE (Bristol). In his opening address LORD EXETER said that there was increasing need in an industrialized world for men to have the opportunity of being fit and healthy, having interesting work to do, and enjoying constructive recreation. If these things were not available the world would soon be populated by neurotics.

Speaking on the need for recreation—in the true sense of the word—the BISHOP OF COVENTRY said that a number of factors were of value in *re*-creation: the first was doing the opposite of one's usual occupation, the second silence—which gave opportunities for reflection and appreciation of beauty—and the third reading. Equally important were faith and service. The present generation desperately needed the breadth of outlook which could be captured through re-creative recreation.

Sport

Sir ARTHUR PORRITT, turning to the role of sport, described recreation as the recharging of life's batteries. To be effective in refreshing the individual, games and other forms of physical exercise had to be fun, and not purposive like so much modern competitive sport. The Olympic Games had exaggerated competition, and the same thing was tending to happen in schools, where games were moving away from amateurism, which was the essence of true recreation.

Sir CHARLES WHEELER put forward the claims of the arts to have therapeutic powers. He quoted from *Painting as a Pastime*, in which Sir Winston Churchill had related the pleasure he found in painting. Sir Charles went on to expand on the joys of exploring what he described as the three kingdoms of colour, form, and light and shade. Within every individual there was the capacity for appreciation of these qualities, and those who wished to explore them could do so through the medium of the arts and be richer for the experience.

Gardening

Professor ALAN R. GEMMELL, discussing what he described as one of the most popular forms of recreation in England, outlined the virtues of gardening. The development of small modern gardens in Britain had followed the industrial revolution and had later spread all over the world. Gardening today owed its popularity to a number of factors. It provided a change of occupation, a means of physical exercise, and the intellectual satisfaction of a creative task.

Reading

Speaking on literature, Mr. **Kenneth Hudson** said that reading should not be regarded just as an anaesthetic or pain-killing drug, for it could give even the most sophisticated person an opportunity to broaden his outlook. He regretted that the experience of people like doctors and barmaids—who knew so much of life—was seldom recorded, and that those who wrote knew relatively little of life. Finally, Mr. Hudson condemned the "literature" which was inflicted on schoolchildren for the sake of examinations.

Music in the Twentieth Century

Professor **Willis Grant** outlined the development of music during the twentieth century. The scales and key systems which had been the basis of nineteenth century romantic music had been progressively abandoned, frequent changes of key giving way to polytonality, which like polygamy showed not rejection but a fondness for the subject. Later developments had included expressionism, atonality—in which keys were finally abandoned—microtones, and complete freedom from any rules governing rhythm or tonality. There were many present-day musicians who earned their living playing Mozart but believed that the future of music lay along these lines, said Professor Grant.

Dr. **William Evans** made the final contribution and spoke on the need for renewing, refreshing, and refurbishing what was weakened and needed strengthening—in this case, medicine. Good doctors were born rather than made through training, and much depended on better selection of medical students. Preclinical studies ought to coordinate the different disciplines, and clinical medicine required recreation of the relationship between doctor and patient. Examination at the bedside was being forsaken and there was excessive advertisement and prescribing of drugs. Dr. Evans suggested that final-year medical students and newly qualified doctors should gain practical experience by spending some months in general practice, and that family physicians ought to work with teaching hospitals in the training of students. Adequate time was the kernel of good doctoring, but the National Health Service did not allow for this and was in urgent need for re-creation.

Maternity Service

Friday, 14 July

A panel discussion on the maternity service was held, with Mr. J. R. **Nicholson-Lailey** (Taunton, Somerset) in the chair. Dr. D. F. **Henley** (Leicester) spoke for the local authority, whose present contact with the maternity service was the provision of midwives. The role of the district midwife had come under review latterly because more confinements occurred in hospital (68% now in Leicester) and more than 20% of patients were discharged early. Each midwife still managed about 50 deliveries a year on the district.

The shortage of midwives had led to the introduction in 1964 of individual radio links between the midwife and the ambulance station at a cost of £10,000. Dr. Henley showed the apparatus to the audience. It could transmit and receive from inside the home over a range of about 10 miles. It had proved of tremendous value. Co-operation between the general practitioner and the local authority was rapidly expanding, but it had not proved possible to attach midwives to specific practices. Attachments to group practices and joint antenatal clinics were working well. Dr. Henley knew that neither the district midwives nor the patients would like a unified and more impersonal hospital-based service.

Looking into the future, Dr. R. P. C. **Handfield-Jones** (Haddenham, Bucks) assumed that domiciliary midwifery would decline but there would always be some. More deliveries would be done in both hospital and general-practitioner units. The perinatal mortality survey had revealed the shortcomings of general-practitioner obstetrics. Selection for domiciliary delivery and equipment for emergencies had not always been satisfactory. However, since this survey had been undertaken 80% of new entrants to general practice had done house appointments in obstetrics, and Dr. Handfield-Jones believed that more rather than less general practitioners would be practising obstetrics in the future. They would regard the supervision of most of the pregnant women in their practice as part of the job.

Role of General Practitioners

Mr. J. A. **Stallworthy** (Oxford) had campaigned to include the general practitioner as a vital member of the maternity service. General-practitioner units now dealt with 10,000 deliveries a year with very low maternal and perinatal mortalities. For planning purposes it was essential to recognize and define the group of high-risk patients. About 25% of those booked for home confinements were eventually transferred to hospital, and this group had the highest rate of maternal and perinatal complications. More education of both the public and the medical staff, more organization to get the right patient in the right place with the right facilities, and more teamwork were Mr. Stallworthy's recommendations for a better maternity service.

Representing the Royal College of Obstetricians and Gynaecologists, Sir **John Peel** was concerned about the relationship between consultants and general practitioners. He felt that the college had sometimes been misrepresented on this matter. It regarded the general practitioner as a vital part of the maternity service. The decrease in domiciliary midwifery meant that some midwives might have as few as five deliveries a year. This raised training problems. There was no future in competition between consultant, general practitioner, and midwife. A B.M.A. survey some time ago had shown that only a third of general practitioners did obstetrics enthusiastically. Sir John thought this figure would be much the same today, although the number of general-practitioner units had increased by 65% in recent years.

Discussion

Questions covered all aspects of the service from the isolation of patients in the hospital to methods of resuscitating babies. Dr. **Handfield-Jones** demonstrated the Blease–Samson resuscitator, which he regarded as essential for all general-practitioner obstetricians. But there was disagreement about whether midwives should be trained to intubate babies. All agreed that flying squads should be available everywhere. Alterations in the existing obstetric list were not regarded as feasible, but Sir **John Peel** said that adequate resident hospital experience was the only true criterion of admission.

Dr. **Henley** summarized the arguments for and against maternity nurses. It was agreed that the creation of two classes of midwives was most undesirable. However, instead of training all midwives in the same way, Mr. Stallworthy thought that those who wanted a career in district midwifery might select areas where more of it was done and have their training directed towards such a career. The legal problems of district midwives delivering patients in hospital and general-practitioner units would have to be overcome. Finally, the question of whether there were enough obstetric patients to provide training for midwives, medical students, general-practitioner obstetricians, and specialist obstetricians was considered. Sir **John Peel** and Mr. **Stallworthy** thought that bringing peripheral hospitals into the orbit of the teaching groups would provide plenty of obstetric patients and tap the experience and ideas of those not at present in teaching hospitals.

Urinary Incontinence in the Aged

Opening a meeting on recent trends in the management of urinary incontinence in the aged, with Mr. J. **Cosbie Ross** (Liverpool) as chairman, Mr. N. O. K. **Gibbon** (Liverpool) described the mechanism of the various types of incontinence and related these to the pathological conditions found in the aged.

Incontinence could be due to defective bladder storage (stress incontinence), failure to empty the bladder (overflow incontinence), and failure of voluntary bladder control (" true " incontinence and nocturnal enuresis). Ideally incontinence should be treated by removing the cause, and when urethral obstruction was present this was often possible. When the bladder had become atonic during recumbency temporary catheter drainage was often effective. In stress incontinence operation was more likely to be successful in the female than in the male, for whom various appliances were available. When cerebral disorders were present much could be achieved by physical and mental rehabilitation, including bladder drill and vesical distension under cystometric control. Anticholinergic drugs, the use of posterior pituitary extract at bedtime, and special urinals made life more tolerable for those with incontinence.

Contributing Factors

Mr. J. P. Mitchell (Bristol) said that some contributing and treatable factors in incontinence of the aged were chronic constipation, chronic cystitis, urinary infection, obstruction, and prostatectomy. The effects of the latter were usually temporary. Three types of patient who were difficult to manage were those who were unsuitable for operation, those who were immobile, and those whose incontinence was due to cortical deficiency resulting from cerebral arteriosclerosis. Mr. Mitchell then described the various types of appliances that could be worn by the incontinent patient. Appliances were of two types, for occasional dribbling between micturition and for total incontinence, appliances for the latter requiring a greater capacity. The apparatus should have some type of valvular control, be made of non-irritant material, and be either easy to clean or disposable. Indwelling catheters should be avoided at all costs.

The last speaker, Dr. T. N. Rudd (Southampton), emphasized that senile incontinence was primarily based not on lesions of the bladder and pelvic floor but on cerebral vascular disturbance. It should therefore be regarded as a functional disturbance analogous to hemiplegia and aphasia. Whenever possible active retraining of the bladder should be undertaken, using sound psychological management and avoiding all discouraging influences. Recently attention had been directed to the role of the pelvic floor in the control of bladder function. Muscular tone in the bladder could now be maintained by physiotherapy and by electronic stimulation of the pelvic floor.

In reply to a question, Mr. Mitchell agreed that patients with indwelling catheters tolerated them longer with prophylactic antibiotic treatment. But eventually they succumbed to infection. Mr. Gibbon considered the catheter a dangerous instrument, although it could be used for quite a long time with frequent changing and bladder washouts. Dr. Rudd thought it desirable to elevate the mood of incontinent patients by the use of suitable drugs.

Rheumatoid Arthritis—Conservative and Surgical Management

A discussion of modern trends in the medical and surgical management of rheumatoid arthritis were introduced by Professor J. H. Kellgren. He defined the disease and outlined its natural history, which followed three main paths: remitting, progressive, and malignant. Any assessment of the effectiveness of therapy had to be made against the background of this variability in the progress of the disease.

Variability was again stressed by Dr. Michael Mason, who said that half the sufferers from rheumatoid arthritis did not suffer from joint deformity, and only about 10% became crippled. Severe cases had an associated vasculitis and this, together with infection, amyloidosis, or atlanto-occipital subluxation might be a cause of death. The treatment of rheumatoid arthritis should include healing the local lesions in the joints, together with management of the general illness and the patient's psyche. It might be possible to help the patient by modifying his environment.

Dr. Mason said that specific therapy with injections of gold or corticosteroids should be considered in those patients with an established diagnosis in whom the disease was active and progressive and in whom symptomatic relief was proving impossible. He recommended corticosteroid therapy in addition in patients with fulminating disease, those with crippling morning stiffness who were finding difficulty in continuing at their work, and those patients who were showing a rapidly progressive destruction of their joints. There was little experience yet with immunosuppressive therapy in rheumatoid arthritis. In a small series of nine patients treated with azathioprine at the London Hospital only one patient had failed to respond when the drug had been given in a dose of 2.5 mg./kg./day, but five patients had eventually to stop treatment because of side-effects.

Surgical Reconstruction

Mr. Douglas Savill stressed the need for co-operation between physicians and surgeons in the management of rheumatoid arthritis. Surgical reconstruction of the damage done by disease which had become inactive had been done for many years. Advances in technique had now made it possible to operate on joints and tendons when the disease was still active. "Prophylactic" surgery could relieve pain, and thus preserve function during early involvement when procedures such as synovectomy might assist progress of the disease.

When the disease was in its intermediate stage surgery might be able to help the patient by allowing him to continue at work. Examples of this were the repair of the painless rupture of tendons that could occur in the rheumatoid hand. Removal of nodules on tendons or prophylactic decompression might enable a patient to maintain good movement of the affected part.

Though the results of a controlled trial of the use of synovectomy in affected knee and metacarpophalangeal joints were not yet available, he thought that many patients obtained considerable symptomatic relief, and that if the operation was done early progress of the disease might be averted. However, he had seen continued deterioration of the joints as judged by their radiographic appearances after synovectomy. The most difficult problem was knowing the right time to operate; in some cases involvement of the cartilage with pannus occurred so rapidly that there was only a fleeting opportunity to intervene with any chance of benefiting the patient.

Medical Films

Films were shown daily during the Scientific Meeting. Several were given a repeat showing, and an opportunity was given for any of the films to be repeated by request. There was a very wide range of interest in the programme, some films dealing with highly technical subjects, while others were more suitable for general practitioners and one or two were intended for showing to lay audiences.

Examples of technical films of specialized interest were "Concomitant Aortic and Mitral Valve Replacement" (Dr. Arthur C. Beall, jun., Baylor University College of Medicine, Houston, Texas), "Myocardial Revascularization" (Dr. Vineberg, Upjohn Ltd.), "Total Replacement of Larynx and Pharynx—an Operation for Carcinoma" (Mr. R. K. Roddie and Mr. H. T. John, Southmead Hospital) and "Intensive Care Regime in a Case of Tetanus" (Dr. G. Quayle). Films of this type can present complex new procedures with a clarity and brevity that cannot be bettered.

More general subjects included "The Treatment of Burns" (Mr. John Watson, Queen Victoria Hospital, East Grinstead), "Topical Steroids in Practice" (Glaxo Laboratories), and "Ankylosing Spondylitis" (Professor S. de Seze, Paris). "Doctor on a Tightrope" (Medical Defence Union) was an excellent example of the way in which a lighthearted presentation can make a strong impression; this film is likely to be of particular value to newly qualified doctors.

"Dead Easy" (Borough of Slough Health Department) was another good film—it won a Silver Award in the B.M.A. Film Competition of 1965—which was of interest and value not only to doctors but also to lay audiences.

Few of the films were new. Most were two or three years old and some considerably older, and in one or two cases it was apparent that, though films, like textbooks, become out of date, they cannot so readily be revised. Of the 21 films shown 11 were award winners in B.M.A. film competitions, and the overall standard was very high. Any doctor prepared to spend an hour or so during the course of the meeting in attending the film theatre could form an excellent impression of the value of this form of teaching in health education and undergraduate and postgraduate training.

Scientific Exhibition

The Scientific Exhibition was the fourteenth to be held in conjunction with the B.M.A. Annual Meeting. It was opened by Mr. Robert V. Cooke, then President-Elect, who made a tour of the 45 stands, of which 16 were from hospitals in the Bristol region.

Prize-winning Exhibits

The Lawrence Abel Cup for the outstanding exhibit was awarded to "The Fractured Malar," from the department of plastic and jaw surgery, Frenchay Hospital, Bristol (Mr. J. W. Ross and Mr. R. T. Routledge). This exhibit was notable for the excellent use of photography to illustrate the method and importance of early recognition and treatment. The cardinal signs and symptoms were clearly demonstrated, and one section was devoted to some of the sequelae which may follow untreated or badly treated fractures.

Certificates of Merit with High Commendation were awarded equally to three exhibits. The first, "Towards Useful Hands," department of plastic surgery, Frenchay Hospital, Bristol (Mr. R. W. Hiles and Mr. M. Deane), was a pictorial demonstration of reconstructive surgery, showing the procedures used from operative technique to rehabilitative physiotherapy. The second in this category was a display, "The Main Characteristics of the Six Common Ringworm Fungi" (Dr. Robert P. Warin, Dr. Clifford D. Evans, Dr. Roger R. M. Harman, and Miss Mary E. English, United Bristol Hospitals), and here again particularly good use was made of coloured pictures clearly set out to show the clinical conditions caused and their characteristic features. The Royal Army Medical College's exhibit from the department of military surgery (Major F. P. Thoresby and Major N. A. Boyd) was the other stand receiving an award in this category. It showed the results of animal experiments comparing methods of treatment of gunshot wounds which had been contaminated with gas-gangrene organisms. High velocity bullet wounds contaminated with spores of a virulent strain of *Clostridium oedematiens* were inflicted on the quadriceps muscle of anaesthetized sheep. Pencillin therapy alone after wounding gave much better survival rates than with surgical procedures with or without penicillin. However, the maximum period of grace afforded by antibiotics before surgery was essential in human gunshot wounds had yet to be established.

Certificates of Merit

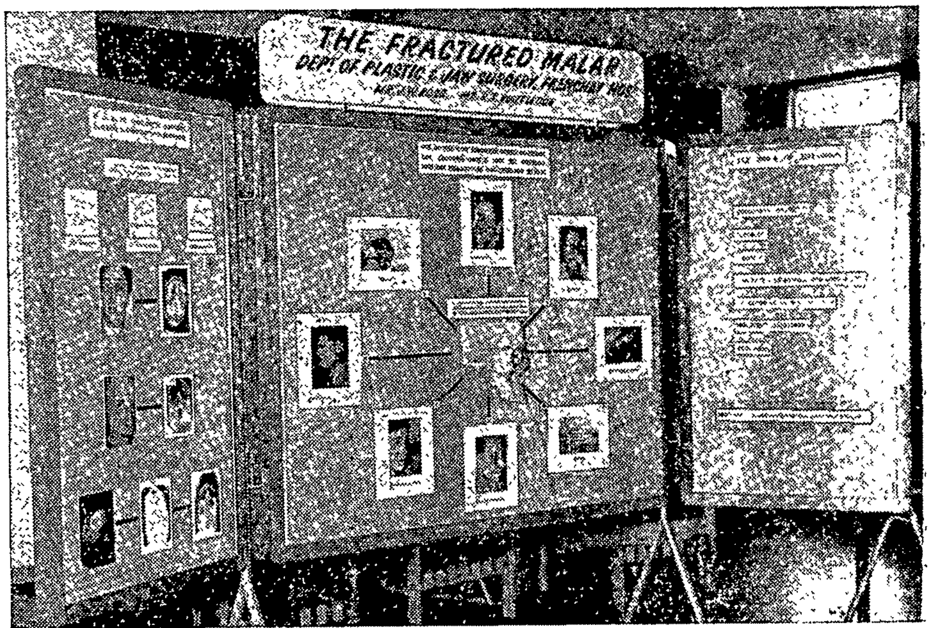
Certificates of Merit were awarded jointly to an exhibit showing the use of "Fluorescein Angiography in Ophthalmology and Neurology" from the neuro-ophthalmic department, National Hospital for Nervous Disease, London (Mr. M. Sanders, Mr. D. Archer, and Mr. T. ffytche); "The Pyloric Regurgitation Test" from the department of gastroenterology, Southmead Hospital (Mr. W. M. Capper, Mr. J. O. Kilby, Dr. Graham R. Airth, and Mr. M. J. Gibson); and "Control of Incontinence by Electrical Stimulation" from the Royal Devon and Exeter Hospital, sphincter research unit (Mr. K. P. S. Caldwell, Mr. P. Cook, Dr. F. C. Flack, and Mr. D. James). Striking photographs demonstrated the use of fluorescein angiography in papilloedema, retinal vascular disease, and neoplastic and degenerative lesions of the retina and choroid. In the exhibit showing control of incontinence the methods of stimulation of muscles involved in both urinary and foetal incontinence were displayed, together with the equipment used.

Malignant Disease

Mr. D. C. Bodenham and Dr. O. C. Lloyd (Frenchay Hospital, Bristol) had used excellent colour photography to illustrate the principal features of malignant melanomas of particular interest to the general practitioner. The importance of sex and age on the incidence at different sites was emphasized. Also from Frenchay Hospital (Dr. R. Sandry and Mr. G. M. Fitzgibbon) was a demonstration entitled "Variations in the Clinical Appearances of Basal Cell Carcinoma." This comprised an excellent series of photographs illustrating the variable manner in which the basal cell carcinoma may present, mimicking conditions such as chronic eczema or malignant melanoma. "Lumps in the Breast" (Professor Francis E. Stock and Mr. J. F. Kane, department of surgery, University of Liverpool) provided another good opportunity for the use of explanatory photographs to assist in the differential diagnosis of this condition. The use of temperature as a method of diagnosis in various breast conditions was demonstrated by the department of measurement and clinical research, St. Martin's Hospital, Bath (Dr. K. Lloyd Williams and Mr. K. D. Patil). The temperature differences created by a tumour were a measurement of its biological activity, and could be influenced by the administration of hormones.

Other Exhibits

A great diversity of subjects were featured on other stands. These ranged from a demonstration of electrical anaesthesia in a goldfish produced by passing a direct current through the tank (Professor John Clutton-Brock, department of anaesthetics, the University of Bristol) to the Royal Naval Physiological Laboratory's presentation of a telemetry system for medical and physiological monitoring (Mr. C. C. Wilton-Davies and Mr. J. D. Andrews). This system is designed for the monitoring of active subjects in the open, in pressure chambers, and in the sea. The department of pathology, the Welsh National School of Medicine (Dr. E. E. Payne and Mr. P. J. Stinchcombe), showed a demonstration of the necropsy findings in the brains of six professional boxers. The punch-drunk state was popularly recognized as one of the hazards of boxing, and many boxers had been examined in an endeavour to confirm or refute its existence. There were, however, very little pathological data to support any hypothesis about the causative lesion. Dr. Peter Samman and Dr. Peter Hansell, of the departments of dermatology and medical illustration, Westminster Hospital, London, contributed an exhibit designed to assist in the recognition of nail disorders, and the conditions they showed accounted for over 80% of all nail disorders seen in practice.



The Lawrence Abel Cup winning exhibit, from Frenchay Hospital, Bristol.

WITHOUT PREJUDICE

I ended last week's piece with the hint that the medical profession had a right to consider ways and means of working in the N.H.S. in terms of enlightened self-interest. My correspondent who said that as a G.P. he would prefer to work on a salaried basis and was well content with his lot qualified in 1952. By the same post I had another letter from a general practitioner (qualified in 1953) telling me he wanted to get into touch with the Belfast doctor whose group had regular sessions with a consultant. He himself worked in a group now periodically visited by a paediatrician.

The efficient organization of work in groups, preferably in close contact with hospitals and consultant opinion, is essential if time is to be available for the proper conduct of clinical medicine. Not only that, but intelligent organization of work is profitable. A striking example of this is shown in the July issue of the *Practitioner*. A general practitioner of what one might call the N.H.S. generation, Dr. T. Russell, transformed the work of his practice by converting a partnership into a group practice. He carried out a time-and-motion investigation of the practice, which he describes as a "study in cost effectiveness."

"It has been said of general practice," he writes, "that it is incapable of being streamlined without detriment to that quality of personal care that a patient expects to get from his family doctor. This dictum is flatly untrue . . . ." The work was concentrated in a highly efficient "group surgery." "Also we have that most blest of all things—an effective examination-room system and technique that effectively trebles or even quadruples our consultation rate." They make selective appointments for their patients, because they have organized time instead of letting time disorganize them. "Thus the sum total of all these measures is a truly astonishing increase in our cost effectiveness. Our profits are high, our patients are happy, *and we have time to spare*" (my italics).

General practitioners ought to found a 1948 club, membership being limited to those who have qualified since that date. Exchange of information in such a group might speed up the changes needed to bring the practice of medicine up to date. The demonstrations by Dr. Russell and many others show how group or health-centre practices properly organized can provide the time for the thorough examination of the patient which must be the basis of the practice of clinical medicine. This must be the primary concern of the doctor. This is what he is trained for. This is what the patient wants. It is this which gives the doctor the continued experience without which his clinical acumen becomes blunted.

* * *

I have been chivvied for giving so much space lately to the problems of general practice. I am unrepentant. If we can get a bit closer to the solutions of the many problems of general practice, then, I believe, the other pieces of the N.H.S. will in due course fall into place. There are now so many excellent models of group practices and health centres that there is surely every reason to take advantage of these ways of doing good work that at the same time is more profitable. Enlightened self-interest demands this. Within the frame provided by the group there are many possible variations that will be determined as much as anything else by geography and the social and industrial environment.

The question of private or public practice in this modern setting of the group practice or health centre is, I believe, irrelevant. In the strict sense of a doctor's ethic every patient is a private patient whatever the source of his pay. Every sick person is entitled to exactly the same consideration—and privacy—as every other sick person. I would make them all private patients in one sense of the old contractual relationship by seeing that all make at least some payment at the time of consultation, with exemption for the young, the old, and the chronically ill. This is done in other countries with national health schemes, and in Russia patients are made to pay for their drugs.

From the group or the centre—especially when the health centre is attached to a district hospital—the general physician with extra ability and training can move into the hospital. And in time he will be able to move into the public health service when its centre is in the medical group and not in the town hall. The public health doctor will then be paid as a doctor.

* * *

Enlightened self-interest must come in at this point. A universal salaried service has for the administrator all the virtues of simplicity. It would bring the doctor effectively under the control of the administrator, of the State. There is a strong political tide seeking to bring everyone down to a level of equality that makes nonsense of human variability. So I would urge my fellow professionals to preserve as wide a field as possible for variety of service and enterprise and energy.

By and large this will have to be within the ambit of the N.H.S. There is only one alternative to the N.H.S. and that is private practice outside it. I think it is a mistake to try to discourage private practice. The amount of private practice will depend very much on the public. It is the right of the patient rather than the right of the doctor. To foster a conflict between private and public practice is a disservice to both. There is every reason for looking at the one as supplementing the other. It would be better, I think, to wed the two in a public N.H.S. financed partly on a basis of charges and with devolution from the centre to the re-formed regions. This would give the Ministry of Health time and opportunity to act as a power-house of ideas. It shouldn't concern itself with details any more than the G.P. should bother with the trivia of practice which can be better handled by others less qualified.

* * *

With the problems of general practice on the way to solution the hospitals wait for their Beeching. In the meanwhile Lord Cohen's proposals in the House of Lords earlier this year should help to stem the flow of emigration. Scrap all existing titles of posts. Establish hospital medical posts of increasing annual seniority and pay. Anyone who has satisfactorily pursued a course of specialist training should be assured of a specialist position at the end of his training, with promotion to senior rank in due course.

I believe that the devising of new ways of making the N.H.S. run efficiently is the first priority. The structure is faulty. It creaks and groans. There's an awful lot of waste to begin with. As Professor Dunlop of Harvard said not long ago of the position in the U.S.A.: "Nothing could be worse in our society today than to say we need another three or five billion dollars for medical care, and then simply duplicate or multiply the arrangements we now have."

* * *

The Director of Simulation and Forecasting Studies at the Rand Corporation in California, known as the "Think Tank," told a group of businessmen in New York recently, "Fatalism is a fatality. The future is no longer viewed as unique, unforeseeable, and inevitable. There are instead, it is realized, a multitude of possible futures, with associated probabilities that can be estimated and, to some extent, manipulated." Among the multitude of possible futures for the practice of medicine the N.H.S. will be there for a long time, until it is replaced in, say, 30 years' time by a European Medical Service. We ought to be making plans for this now. *Vale!*

Post-concussional Sequelae

SIR,—I find it difficult to correlate Mr. A. R. Taylor's opinions on the post-concussional sequelae (8 July, p. 67) and some points in your leading article on the same subject (same issue, p. 61) with my general neurosurgical experience, which includes a great number of patients with both civilian and military head injuries. I believe that the so-called "post-concussional syndrome" is unlikely to be caused by neuronal damage; it was rarely seen in penetrating head wounds and it is not a feature following operations which stretch the brain stem—for example, the removal of an acoustic neurinoma. In surgical posterior fossa lesions "head dizziness" is not common; the dizziness these patients refer to is most frequently due to cerebellar unsteadiness of the legs. White fibre damage in other areas of the brain does not cause either constant or postural headache.

In head injuries with clinical evidence of neural damage (psychometric deterioration, limb weakness) it is usually the family rather than the patient who seek medical advice. These patients tend to become facile and less concerned with their future. The reasons why patients after even mild head injury are more frightened than patients with injuries to other parts of the body was long ago discussed and explained by Paul Schilder.[1]

I believe that in the "post-concussional sequelae" spasm of the nuchal muscles plays a dominant role, whether the headache be constant and dull, as in the majority of compensation cases, or be brought on by bending of the neck. This assumption can readily be proved by the invariable tenderness of muscles at the back of the neck and the prompt, if temporary, relief of headache in non-compensation cases by the injection of local anaesthetic, the wearing of a collar, and physiotherapy. The tension is also responsible for the dizziness and headache; dizziness which may culminate in frequent blackouts. These are the somatic expressions of psychogenic tension, mainly a fear that another head injury might occur, and the gain motive plays a large part in compensation cases. The headache and dizziness coupled with unemployment lead to irritability and forgetfulness which I should not call "neurotic," for the patient's personality remains essentially intact and can quickly return to normality when his claim has been settled. I agree with Professor Miller's[2] appreciation of the syndrome in compensation cases. It would be unfortunate if the present annual increase of compensation cases were to receive encouragement from your articles.

In conclusion, I plead that Trotter's[3] definition of concussion be adhered to.—I am, etc.,

J. SCHORSTEIN.

Hetacillin and Ampicillin

SIR,—The vigour of the pharmaceutical industry has produced a flood of antibiotics, but often the problem for the prescriber is to distinguish the significant from the insignificant new drug before confusion arises. The report by Mr. R. Sutherland and Dr. O. P. W. Robinson (24 June, p. 804) on hetacillin (Versapen) is therefore timely. Hetacillin has been launched as a new broad-spectrum, semi-synthetic penicillin with properties similar to those of ampicillin (Penbritin). This similarity is neither disputed nor surprising, for hetacillin is in large measure converted to ampicillin in the body and in neutral aqueous solutions generally. It follows, therefore, that any therapeutic significance for hetacillin, as an alternative to ampicillin, must depend on whether or not absorption and blood concentrations are greater with hetacillin. Reports from America, where hetacillin was developed, make this claim[1]; the results of Sutherland and Robinson show the opposite.

I have recently compared blood levels of ampicillin and hetacillin in a crossover study in which 12 healthy human volunteers were given 250 mg. of each drug on separate days. Blood levels were measured by a standard cup plate assay method, using large plates seeded with *Sarcina lutea* and control solutions of each antibiotic made up in normal human serum. The results shown below confirm the findings of Sutherland and Robinson that absorption of ampicillin is more rapid and leads to higher blood levels compared with hetacillin.

Mean Serum Concentrations in 12 Human Subjects

Antibiotic	Mean Serum Concentration (µg./ml.)				
	½ hr.	1 hr.	2 hr.	3 hr.	4 hr.
Ampicillin, 250 mg.	1·14	1·89	1·95	1·24	0·64
Hetacillin, 250 mg.	0·07	0·39	0·95	0·96	0·47

Consideration of the differences between the serum concentrations following the administration of ampicillin and hetacillin at each interval of time, in each individual, goes some way towards explaining the discrepancy between the results reported from America and quoted by the manufacturers of hetacillin, and those of Sutherland and Robinson. These differences, calculated by subtracting the lowest serum concentration from the highest for each individual at each interval after the administration of each antibiotic, are shown below.

Differences (in µg./ml.) Between Serum Concentrations After 250 mg. Ampicillin and Serum Concentration After 250 mg. of Hetacillin in 12 Subjects

Subject	Interval after 250 mg. Doses				
	½ hr.	1 hr.	2 hr.	3 hr.	4 hr.
1	1·16	0·71	*(0·17)*	*(0·03)*	0·43
2	0·22	0·7	1·55	0·51	0·53
3	1·11	1·42	1·57	*(0·02)*	0·25
4	0·27	0·6	0·62	0·45	*(0·11)*
5	0·31	2·70	2·54	0·9	0·4
6	3·43	4·2	*(0·7)*	*(0·78)*	*(0·11)*
7	0·02	0·85	1·37	0·62	0·14
8	1·5	2·38	0·77	0·07	0·26
9	0	0·33	1·65	0·69	0·37
10	2·06	2·65	0·75	0·15	0·02
11	1·16	0·73	1·20	1·0	*(0·04)*
12	1·83	0·80	0·81	0·06	*(0·03)*

Note: The nine sets of figures in brackets indicate the occasions on which the serum concentrations were higher following the administration of hetacillin than following ampicillin. In all other instances the serum concentrations were higher after the administration of ampicillin.

It will be seen that in only nine instances out of 60 did the serum concentration after hetacillin exceed that following the administration of ampicillin. Furthermore, in these nine instances the difference was very small and probably within the range of error of the method. Subject 6 appears to be an exception, because in this subject the serum concentration following hetacillin exceeded that following ampicillin by 0.7 µg./ml. at two hours and by 0.78 µg./ml. at three hours. This subject was, however, an exceptionally good absorber of both drugs and a peak level of ampicillin of 5 µg./ml. was achieved after one hour, while the peak level of hetacillin was 3.1 µg./ml. at three hours. In all 12 subjects the peak concentration achieved after ampicillin exceeded the peak concentration after hetacillin, usually by a very significant amount; also the peak concentrations of hetacillin tended to occur later than those of ampicillin.

I conclude, therefore, that hetacillin generally gives lower blood concentrations than ampicillin, and that it does not have significant new properties. It does seem that there is a continuing need for an organization which is prepared to carry out or arrange objective assessment of conflicting reports on the properties of antibacterial agents.—I am, etc.,

MARK RIDLEY.

Investigating Hypertension

SIR,—Your recent leading article (1 July, p. 4) entitled "Investigating Hypertension" appears to give a somewhat incomplete and misleading impression of the current position in this field. Indeed, it is a little difficult to see what point your writer is trying to make.

When is investigation of hypertension "fruitless"? Apparently when continued after "the small number of potentially curable patients" have been detected—the others are to be spared. You go on to suggest that the I.V.P., "supplemented by radiographs taken during the first five minutes of the examination" (surely standard practice for years ?), together with a radioisotope renogram, may be the best way of selecting those who may benefit from further inpatient investigation.

If such a practice were to be universally adopted there would be little progress in the field of hypertension. You make no reference to the complex biochemical problems which offer a considerable challenge to physicians currently engaged in this work: into the problems of recognizing aldosteronism in its various forms; or in detecting pressor-secreting tumours of the adrenals or kidneys—conditions which could not possibly be identified using the screening procedures you suggest. Nor do your comments contain more than scant reference to the merits of aortography, though you quote the series described by Chamberlain and Gleeson.[1] Those authors chose the rather curious parameter of surgical benefit ultimately acquired by the hypertensive patients they investigated with which to judge the value of aortography in hypertension. Quite apart from the smallness of their series and its highly selected nature, it was surely a novel approach for the radiologist to demur on the grounds of doubtful ultimate surgical benefit. There are analogies in other fields where surgical benefit may ultimately be small, such as gastric carcinoma or bronchial carcinoma, but few would suggest that full assessment was unjustified. In any event, medical benefit, in the form of accurate diagnosis and consequent more definitive medical management, might result.

Surely we must get our priorities right. In good clinical practice accurate diagnosis must come before treatment whenever possible, and we should avoid the temptation to attempt to short-cut what is usually a rather painstaking and detailed inquiry. Thus without angiography it may be impossible to identify such conditions as fibromuscular dysplasia, renal-artery aneurysm, thrombosis or embolism in a branch of the renal artery, or renal-artery anomalies. These latter are exceedingly common, and, we believe, important. We have published two papers in which these aspects have been discussed, though you refer to neither.[2 3]

It is agreed that many difficulties surround the practical aspects of investigating hypertension, but surely the decision is still a clinical one. If the patient has hypertension sufficiently significant in the physician's judgement to warrant treatment then investigation should usually be undertaken first. If this is to be done at all then it should be complete, and requires full biochemical and radiological assessment in most instances. We are not impressed by the arguments that this is impracticable, for it is not too difficult to organize facilities to this end, and the procedure need be done only once in the lifetime of most of the patients. About 1,000 patients have been assessed in some detail (including the procedure of aortography) in recent years as part of the general medical work at this hospital.—I am, etc.,

PHILIP W. ROBERTSON.

Royal Air Force Hospital,
Wolverhampton,
Staffordshire.

*** The leading article was concerned with the initial detection of renal lesions that may be responsible for hypertension, and the problem of selecting patients for further inpatient investigation into a renal cause for their disease. It did not discuss topics such as the investigation of aldosteronism; there is of course no suggestion that other than renal causes should be overlooked in the assessment of the hypertensive patient. We regret not referring to the papers[2 3] by Wing Commander Robertson and his colleagues, though both papers have been criticized by workers unable to confirm his group's findings.[4] He has commented on this.[5] Many doctors would disagree with Wing Commander Robertson's suggestion that the hypertensive patient who is to be treated should "in most instances" undergo complete radiological investigation, including aortography, as he implies. This is one of the points the leading article was at pains to make. Even in young hypertensive patients, the group in whom vigorous investigation is most promising, the preliminary report of a recent survey[6] shows the small returns to be gained from renal arteriography in the presence of a normal pyelogram.—ED., *B.M.J.*

Accident Service

SIR,—No doubt much wisdom was spoken at the symposium on accident service at the Annual Meeting (see 22 July, p. 230), but the points of emphasis which reached the national press and television suggested a derangement of the priorities.

Surely we must accept as a first priority the proper care of the millions of injured who attend the hospitals each year. This means emphasizing as the number one need sufficient suitably staffed and equipped departments in designated hospitals to apply modern standards of treatment to the injured. Shortage of money or other priorities, or both, seem likely to stand in the way of this being achieved for many years.

Accident ambulances with special equipment have been tried by this and other units, and given up. Standard equipment for ambulances and general intercommunication between hospital and ambulance would be a valuable development. This will be achieved only with a National Ambulance Service. Helicopters will not make any significant contribution to the management of the injured. Of those who died before getting to hospital in this area, an investigation carried out about five years ago led to the conclusion that in nearly 80% death occurred within ten minutes of the injury. Nothing but prevention could have saved these people.—I am, etc.,

J. C. SCOTT.

Accident Service,
The Radcliffe Infirmary,
Oxford.

Coroner's Verdict and Industrial Compensation

SIR,—I followed with interest the correspondence in the *B.M.J.* relating to Dr. Gavin Thurston's article in the Current Practice section "Reference to the Coroner" (6 May, p. 361). Dr. N. F. Coghill (3 June, p. 637) and Mr. R. S. Murley (17 June, p. 764) make valid criticisms of the reference system and also valuable suggestions about how it could be improved.

As industrial medical officer to a large asbestos textile manufacturer, I am involved in the follow-up of employees receiving benefit for asbestosis reported to the coroner after death.

Mesothelioma of the pleura is now a prescribed disease. As this is a rare condition and as there is world-wide interest in its occurrence, the Working Group on Asbestos and Cancer under the auspices of the Geographical Pathology Committee of the International Union Against Cancer (U.I.C.C.) made certain recommendations regarding its diagnosis, and a consultative panel of pathologists was set up in Great Britain to whom all cases should be referred.[1]

Recently I learned of a coroner recording a verdict of death from mesothelioma of the pleura due to exposure to asbestos on the basis of the coroner's pathologist's report, when evidence was produced at the inquest that the Pneumoconiosis Medical Panel (P.M.P.) did not consider this to be the case. Neither the P.M.P. nor the coroner's pathologist found evidence of asbestosis. The histological sections were examined by a member of the consultative panel of the U.I.C.C., who diagnosed adenocarcinoma of the lung in the absence of asbestosis, confirming the findings of the P.M.P. The coroner preferred the opinion of his own pathologist.

The questions raised by this verdict are of wide-ranging consequence. The dependants of the deceased, if any, will be denied death benefit by the Ministry of Social Security irrespective of the coroner's verdict, as the P.M.P. do not consider death due to mesothelioma. The dependants might feel justified to appeal against this decision on the basis of the coroner's pathologist's opinion. No matter which way the local appeal tribunal decides, should they appeal, the case will probably eventually have to be decided by the Industrial Injuries Commissioner. The above sequence of events need not occur if the coroner accepts that the opinion of the P.M.P. and his pathologist differ, and asks for the opinion of the consultative panel of the U.I.C.C. before recording his verdict. The coroner's verdict, if it differs from the P.M.P. decision, is likely to lead to unnecessary confusion and distress on the part of the relatives and dependants. Both the P.M.P. and the coroner's pathologist very kindly discussed this case with me, and both presented solid reasons for their opinions.

The coroner does not always wait for a report from the P.M.P. before deciding his verdict. Many pathologists do not prepare the lungs adequately before examining them and do not make use of the consultative panel of the U.I.C.C. in doubtful cases of mesothelioma. Why does the coroner have to insist on a quick answer for the cause of death, thus not allowing adequate investigation in cases of this nature ? Why does the coroner have to pronounce his verdict at all in these cases, when there exists a panel of experts more qualified to decide—that is, the P.M.P. or the U.I.C.C. Consultative Committee ?

Dr. Thurston points out that " recording of causes of death is important for the national statistics on which so many calculations and decisions depend." The asbestos industry is fully aware of the health hazards associated with it, but inaccurate death certification can only serve to give the wrong impression and harm an enlightened industry producing a product for which in many instances there is no known substitute.—I am, etc.,

Avoidable Hazards

SIR,—Your leading article " Asbestosis " (8 July, p. 62) was most timely. It is probably not realized that asbestos is used by some dental surgeons in postoperative packing materials following the operation of gingivectomy. It is very likely that a considerable number of dental nurses are exposed to quite heavy concentrations of powdered asbestos in the preparation of these dressings. I have noticed that some nurses shake the bottle before opening. A white cloud of fine asbestos powder appears immediately the lid is removed.

As there are other dressing materials available which do not contain asbestos and which are just as good there is no justification in continuing to use these preparations.—I am, etc.,

Leeds 16. JOHN E. DEB. NORMAN.

Chloasma and the " Pill "

SIR,—Dr. D. B. E. Quamina observed (3 June, p. 638) that chloasma is becoming more common as a side-effect of oral contraceptives, especially in Caucasians living in sunny countries. He says that very little reference has been made to this contraceptive chloasma and believes that analysis of a large series may help to determine whether it is the oestrogen or the progestogen in the pill which causes this complication. This presupposes that only one of these hormones is culpable. Oestrogen alone can cause chloasma, even in the male,[1] but I have not come across chloasma caused by progestogen in the absence of oestrogen. It is my opinion that the progestogen acts on the oestrogen-primed melanocytes,[2] and that chloasma is most likely to be precipitated by sunlight in chloasma-prone patients who have been taking anovulants for a long time, or in high dosage. Thus marked chloasma has been reported from Europe after as little as three months' medication with the large doses of anovulants sometimes used to control gynaecological troubles[3]; and several surveys have shown that the incidence of chloasma increases with the length of time for which the anovulant has been taken.

From various series already published it can be concluded that, for a given oestrogen dosage in a " combined pill," the greater the dosage of progestogen the greater the incidence of chloasma. Changing from one brand of anovulant to another would thus be of no help unless there was a reduction of hormone dosage. Chloasma can also be caused by " sequential therapy." [4]

Dr. Quamina, in Trinidad, is in an excellent position to help to unravel the chloasma mystery. The incidence of chloasma among the anovulant-taking women of another Caribbean island (Puerto Rico) is reported to be as high as 34%.[4] Is there a similar percentage among the natives of Trinidad ? I had imagined that the most deeply pigmented races would be chloasma-free, but it has been stated[5] that chloasma can be seen frequently in the African negro woman if a careful examination is made.—I am, etc.,

Antinuclear Factors

SIR,—The comment in your leading article on " Antinuclear Factors " (10 June, p. 654) that " despite the absence of any certain evidence it may be safely concluded that they have some role in the pathogenesis of [connective tissue] disease " is in our view incorrect.

Only 84% of patients suffering from systemic lupus erythematosus, 81% of patients with systemic sclerosis, and 35% of patients with discoid lupus erythematosus have antinuclear antibodies, even in the active phase of the disease.[1] The titres of antinuclear antibodies are not necessarily proportional to the activity, progress, or treatment of disease.[2] These antibodies are found in several diseases and no antibody is characteristic of any particular disease. They are found in symptomless relatives of patients suffering from connective tissue diseases[3, 4] as well as 4% of control subjects not suffering from connective tissue diseases.[1] Antinuclear antibodies cross the placenta without harming the foetus or newborn child,[5-7] and have been transfused into human volunteers without causing disease.[8-10] Transfusion of serum containing L.E. cell factor does not cause any damage to rats made tolerant to human serum proteins[11] nor does it inhibit the growth of cells in tissue culture.[12-13] Thus there is no evidence that antinuclear antibodies can initiate tissue damage.

Nevertheless, tests for antinuclear antibodies are valuable in clinical practice. In a recent assessment of the value of one test (the rat liver immunofluorescence test) we[14] have found that the connective tissue diseases can be divided into two groups. The first group includes disorders like systemic and discoid lupus erythematosus and systemic sclerosis in which high titres of antinuclear factor are frequently found, and the second those diseases like polyarteritis nodosa, various types of vasculitis, and dermatomyositis in which antinuclear factor is usually absent. We concluded that (*a*) the presence of antinuclear factor in high titre (more than 1 in 64) usually indicates a connective tissue disease such as systemic or discoid lupus erythematosus, systemic sclerosis, Sjögren's syndrome or rheumatoid arthritis, and almost certainly excludes polyarteritis nodosa or dermatomyositis ; (*b*) patients with a titre of 1 in 64 or higher and showing no or few abnormal symptoms or signs should be followed for a long time because they are at risk to develop a connective tissue disease of the first group ; and (*c*) in the absence of any other evidence of connective tissue disorder low titre antinuclear antibodies (1 in 16 or less) can be ignored.

The role of antinuclear antibodies in human disease has still to be determined—We are, etc.,

Combined Antifungal and Antibiotic Therapy

SIR,—Professor P. C. Elmes's assertion in *Prescriber's Journal*[1] that " one in five strains of *Monilia* are resistant to nystatin " has been refuted effectively in the pages of the *B.M.J.* by such distinguished and authoritative writers as Professor E. Drouhet (18 March, p. 699), R. Holt and R. L. Newman, G. T. Stewart, and H. I. Winner (1 April, p. 51). We are in full agreement with these previous correspondents, having in 11 years of extensive use of nystatin encountered many therapy-resistant patients, but no resistant strains of *Candida albicans*. Permit us, however, to comment on another aspect of P. C. Elmes's article which has received rather less attention.

Professor Elmes considers that " antifungal agents are only necessary in serious infections or if local lesions persist after the tetracycline is stopped. . . . Combination tablets such as Mysteclin or Lederstatin are therefore unnecessary. . . . " Fleeting reference is made to systemic candidiasis, but the practitioner is left without guidance about the prevention of such dissemination in patients receiving prolonged antibiotic therapy. Combined anticandidal and antibacterial therapy is strongly indicated in patients in whom oral and gastrointestinal candidal reservoirs may become a focus for systemic invasion or widespread mucosal and cutaneous involvement. This applies particularly to infants with a history of oral, cutaneous, or gastrointestinal candidiasis, as well as to patients with debilitating diseases predisposing to candidal infection (diabetes mellitus, leukaemia, etc.). Such patients frequently receive prolonged antibiotic therapy, and the combination of nystatin with tetracycline is prudent here in order to prevent systemic candidal dissemination from gastrointestinal foci. Systemic candidiasis is markedly underdiagnosed ; in P. C. Elmes's own words, it is "seldom suspected . . . and . . . the diagnosis is usually made at autopsy."[1] Yet systemic candidal infections are increasing in frequency, particularly among patients with leukaemia and lymphomas. A 15-fold increase of such infections in the past decade was revealed by necropsy studies at an institution devoted to the treatment of malignant diseases.[2] We ourselves have recognized more than a score of such cases during the past few years at a 400-bed general hospital in New York City. As many as four patients at a time have been under treatment in the wards, some of them successfully.[3]

The cost tables given by Professor Elmes show that combinations of nystatin and tetracycline (Mysteclin, Lederstatin) cost only slightly more (29s. 3d.) than tetracycline capsules alone (22s. 6d.). Although the price of nystatin is not listed, the cost of administering the two antibiotics separately would probably be considerably higher.

Possible improper or promiscuous use by some practitioners of a useful combination does not warrant its removal from the pharmacopoeia. This would be as illogical as the removal of parenteral penicillin because too many injections are given. Good therapy demands the thoughtful prescription of drugs that fit the needs of a carefully investigated patient suffering from a specific type of infection. There are instances when the combination of an antibacterial and an antifungal agent is the treatment of choice, or when possible error on the side of prudence is preferable to a perfect diagnosis made post mortem.—We are, etc.,

Protective Helmets and Traumatic Epilepsy

SIR,—Two points call for comment in the interesting article by Dr. R. H. P. Fernandez (24 June, p. 830). The case for "skidlids" for motor-cyclists has been argued on statistics which showed how seldom severe head injuries occur in victims who have been wearing a protective helmet. If Dr. Fernandez, with the large amount of data which he evidently has for industrial head injuries, could quote the incidence and mortality of injuries in men wearing helmets it might strengthen the case for compulsory protection in certain occupations. It would also be interesting to know the number of unprotected victims for whom helmets had been recommended, and perhaps even provided, by the management, and who had ignored this advice. Certainly it is an impression that helmets are much more widely worn in Continental Europe and in the U.S.A., at least in the building industry, which is seen at work by the passing tourist.

Dr. Fernandez rightly devotes space to the problem of traumatic epilepsy, which is one of the commonest causes of permanent disability—that is, non-employability—after head injury. Because this often develops in patients who have otherwise fully recovered, it is particularly important to understand its natural history in order to advise both the patient and his employer. Dr. Fernandez quotes Caviness as having shown that in many patients the epilepsy is a temporary affair with a good prospect of remission. However, this conclusion was based on a study of gunshot wounds from the first world war, and there are many differences between this population and civilians suffering blunt head injury. I have previously discussed in these columns the prediction of epilepsy after blunt injuries.[1] Elsewhere I have emphasized the less favourable outlook for remission after blunt head injury compared with missile injuries.[2] Briefly, early epilepsy (within a week of injury) has a 75% chance of permanent remission, but epilepsy developing later (whether or not there has been early epilepsy) persisted in more than 80% of 200 patients followed up for more than two years after their first fit. For the industrial medical officer the practical implications of this are that if a man does develop epilepsy he should be permanently redeployed in a job which is compatible with the occurrence of an occasional seizure, rather than offered temporary arrangements in the belief that the epilepsy will soon cease to be a problem.—I am, etc.,

Enuresis and Psychiatry

SIR,—May I add to the points made by Dr. Ian G. Wickes (15 July, p. 176) ?

Enuresis is one of those bastard problems which are tossed from one physician to another, each hoping that he will not be left with the baby. First we make a vain search for physical cause ; then a quick pass to the paediatrician ; child-guidance follows with electric gadgets ; and finally the psychiatrist. The problem drops back into our laps, so we bless the statistician and say: "He will probably grow out of it by the time he is 10."

The common factor in all the methods of approach mentioned above—and they all have their successes—is suggestion. Opinions on the dangers of symptom removal, although academically valid, make nonsense in light of our daily practice.

The surgeon treats belly-aching by removal of a normal appendix ; our gynaecological colleagues cure a multitude of troubles by diagnostic measures alone. In psychiatry is it not possible that we are merely relieving the symptom of depression when we use our modern drugs ? We are certainly not curing a disease.

Enuresis is not a hopeless problem. Those who are interested will find that a high rate of success can be achieved in family practice. Patience is essential, along with an established personal relationship with the patient ; but record-keeping, conditioning, bribery in the case of the child, suggestion, drugs, and even electric pads will bring success in a majority of cases.—I am, etc.,

Dundee,
Angus.

R. A. B. RORIE.

Unusual Examples of Adnexal Torsion

SIR,—Torsion of the lateral part of a Fallopian tube after sterilization was first reported by Kohl.[1] Since then other cases have been described.[2-4] It is difficult to say if the part of the tube which twists is healthy before the torsion, or whether it is the seat of a hydrosalpinx. However, the division of the tube deprives the lateral part of any stability which it might obtain from continuity with the medial part, thus facilitating torsion. In this context the following case is of interest.

A 31-year-old prediabetic housewife was Rhesus-negative. Her third baby was affected by maternal antibodies, and survived after an exchange transfusion. The mother was subsequently sterilized in 1963. For nine months before admission she suffered from recurrent abdominal pain, and had been treated for biliary colic, although the biliary tract had not been investigated.

She presented as an emergency with pain and vomiting. Her temperature was 101° F. (38.5° C.). There was tenderness in the right iliac fossa, but no peritonism. A tender cystic mass 3 in. (7.6 cm.) in diameter was found in the right anterolateral fornix. At laparotomy it was noted that a Pomeroy operation had been performed. The lateral part of the right Fallopian tube was cystic and gangrenous, and twisted five times on its mesosalpinx. The biliary tract was healthy. Right salpingo-oophorectomy was performed and the specimen mounted for museum display.

Sterilization by the Pomeroy technique is already under criticism. The pregnancy rate may be 1.7%,[5] while Drake has drawn attention to the occurrence of ectopic pregnancies.[6] Salpingectomy would not guarantee prevention of subsequent pregnancy in or outside the uterus, but would remove the risk of tubal torsion.

A 23-year-old housewife complained of deep dyspareunia after the birth of her first child. The uterus was found to be retroverted, and the ovaries had prolapsed into the pouch of Douglas. The uterus was anteverted without difficulty in the clinic, and a No. 8 Hodge pessary inserted into the vagina. Two hours later the patient developed lower abdominal pain and vomiting. She returned to hospital next day. Her temperature was 98.8°F. (37° C.). There was slight tenderness in the left iliac fossa, but no peritonism. The uterus was still anteverted, but behind it was a tender cystic mass 3 in. (7.6 cm.) in diameter. At laparotomy the left tube and ovary were found to have undergone torsion through one turn and to be gangrenous. The right ovary contained a few small cysts, and lay in the pouch of Douglas. Left salpingo-oophorectomy was performed and the round ligaments shortened. The right ovary was then stitched to the pelvic brim. Microscopy revealed that the left ovary was largely replaced by a cyst 6 in. in diameter.

This case demonstrates a simple mechanical aetiology only too well. No comparable report has been found in the literature.

These patients were admitted to Queen Mary's Hospital, Roehampton, London S.W.15, under the care of Mr. R. D. de Vere. I am grateful to him for his advice and help.

Down's Syndrome in India

SIR,—I was interested in your leading article "Worldwide Study of Malformations" (1 April, p. 3). I was surprised that no case of Down's syndrome (mongolism) was found among 70,000 births reported from Alexandria, Bombay, and Calcutta. I have been working with neonates for several years, and have found the incidence of Down's syndrome to be almost the same as reported from the West. In a study of 4,353 newborn infants[1] there were six infants with Down's syndrome—i.e., 1.4 per 1,000 births. The incidence is the same in more recent data collected last year. We have one case of Down's syndrome for 750 births. The incidence of other malformations in the report mentioned above was: musculoskeletal system 1.47% (talipes 19; polydactyly 18); central nervous system 0.9% (anencephaly 13, meningomyelocele 9); digestive system 0.6% (harelip 5, cleft palate 3, both combined 4); skin 0.5%; and urogenital system 0.2%. The overall incidence was 3.4%.—I am, etc.,

Tolerance to Mandrax

SIR,—Dr. R. D. L. Ewart and Dr. R. G. Priest (8 July, p. 92) have shown that the withdrawal of Melsedin (methaqualone) in a dependent patient can lead to delirium tremens similar to that seen in barbiturate dependence. We wish to present evidence indicating that tolerance can be acquired to methaqualone, just as to the barbiturates.

We have previously reported[1 2] the features of methaqualone overdosage in 29 patients admitted to this hospital during a seven-month period immediately following the introduction of Mandrax (methaqualone and diphenhydramine) to this region. There was good correlation between the severity of poisoning and the plasma levels of methaqualone, which at admission ranged from 0.2 to 3.1 mg./100 ml. (mean, 1.5 mg./100 ml.). Levels exceeding 3.0 mg./100 ml. were regarded as dangerous. At the same time it was pointed out that this relationship would probably not hold if tolerance to the drug developed.

That this has indeed happened is indicated by a survey of a further 78 cases of Mandrax poisoning treated after the 29 already reported. From June to December 1966 28 patients were admitted with levels ranging from 0.2 to 3.5 mg./100 ml. (mean, 1.7 mg./100 ml.), and from January to June 1967 50 patients with levels 0.2 to 8.3 mg./100 ml. (mean, 2.3 mg./100 ml.). In spite of this significant rise in mean plasma level very few of these patients showed the features of severe poisoning which characterized a high proportion of the previous series of cases. Since there have been no changes in the policy governing the admission of poisoned patients, in the criteria of clinical assessment, or in laboratory technique, we conclude that the data reflect the development of tolerance—and this, in a population for which methaqualone has been actively prescribed over a period of barely two years.

It is relevant that methaqualone levels of about 10 mg./100 ml. have been found in at least two non-fatal cases of poisoning. Ibe[3] specifically described one such patient as an addict; it seems feasible that habituation, even if not addiction, was a factor in the case described by Caridis[4] and Young.[5]

We have drawn attention[6] to the difficulties and dangers of attempting to correlate the severity of barbiturate poisoning with blood levels; tolerance is no less a problem with methaqualone than with the barbiturates. We have, however, not yet encountered withdrawal features indicating physical or psychic dependence on methaqualone.—We are, etc.,

Common Market—a Challenge, not a Danger

SIR,—I would like to endorse warmly the letter by Dr. S. R. Scagliola (8 July, p. 108). For some time now I have been both amused and mildly irritated by the fears of many colleagues that entry into the Common Market would mean the invasion into Britain of very large numbers of Continental doctors.

The facts are, very simply, that on the whole professional earnings are higher on the Continent than in Britain, and this would seem an adequate disincentive. This does not hold true for the bright graduates in university appointments; their financial plight is in many countries, including Italy, quite serious and undoubtedly a number of them would like to hold paid appointments in research institutes and the better hospitals in Britain. This could not be taken as a threat to our standards and professional financial prospects should some of them wish to remain here and pursue a hospital or university career, as they would have to run the gauntlet of our appointment committees in healthy competition with British qualified doctors.

I would take it that if they wish to enter general practice the General Medical Council would require a year's pre-registration appointments in approved hospitals, and this would be an adequate safeguard.

London W.C.1.

Treatment of Choriocarcinoma

SIR,—The reply of Professor W. S. Tow and Mr. W. C. Cheng (10 June, p. 699) to my letter (15 April, p. 178) requires no modification of my comments on their paper (4 March, p. 521), and I would like to try to clarify the situation.

Following surgical evacuation of a mole some trophoblast usually persists within the uterine wall. It exhibits a wide spectrum of activity, ranging from a local infiltration of cells detectable in some cases only by their endocrine activity, to the large villous masses, hypervascularity, and metastases of invasive mole in others. Choriocarcinoma is thought to occur in about 2% of cases in Britain, and it arises mainly in those with disease which remains subclinical. If choriocarcinoma does not develop the trophoblast tends to die out within three or four months, but it may still die out after persisting for even longer. Non-choriocarcinomatous proliferations may require radical treatment (hysterectomy or chemotherapy) to relieve symptoms or to prevent destruction of the uterus, or because they cannot be distinguished clinically from choriocarcinoma. The greater the interval after a mole has been evacuated the greater the risk that continued trophoblastic proliferation is, or will become, choriocarcinoma. Choriocarcinoma sometimes kills only two to three months after evacuation of a mole, but if treatment is started before irreversible damage has occurred, and within six months of evacuation, current methods of treatment are virtually always successful. If delayed till more than about six months after evacuation therapeutic failures still occur, and instead of chemotherapy lasting only three to four months it may then go on for one to two years before the patient's ordeal ends in either full health or death.

If all the sequelae of mole could be prevented by completely safe chemotherapy this would have advantages, particularly in countries where follow-up is impossible, but the safety and effectiveness of routine prophylactic chemotherapy has not yet been established. The generally practised alternative requires treatment of selected cases. Case selection introduces arbitrary decisions, because the risk of continued observation has to be balanced against the wish not to treat unnecessarily.

It is clear from what Professor Tow and Mr. Cheng tell us that their basis of selection for radical treatment is considerably wider than ours, and it therefore includes cases who would be treated conservatively here. Their reasons for their wider selection may be perfectly sound in Singapore. Further, there has never been any doubt that hysterectomy is usually effective for invasive mole; but whether it is appropriate depends on the patient's age and whether she has children. It is appropriate more often in Singapore than in the United Kingdom for these social reasons. Tow and Cheng argue that because invasive mole is sometimes followed by choriocarcinoma it therefore *is* early choriocarcinoma and carries the same prognosis and requirements for treatment as choriocarcinoma. Having defined choriocarcinoma so as to include a group which is acknowledged to respond to hysterectomy, it is hardly surprising they find it more useful than those who do not include such a group within their treatment series and who prefer to use the term choriocarcinoma in its recognized sense. The criteria of Tow and Cheng for hysterectomy, applied to our series, would result in fewer hysterectomies being performed. Hysterectomy should be reserved, as they themselves assert, for selected cases and not used in childless women who do not need it or in patients with advanced disease who die as a consequence of it.

Far more important than a contrived argument about hysterectomy is the problem of ensuring the effective follow-up of all mole cases, so that patients who need treatment receive it before the chance of recovery is lost. Patients still die because the follow-up methods available are inadequate or not even used. A reliable centralized follow-up system could now be devised with the technology available in the United Kingdom. There is a case for making hydatidiform mole a notifiable disease.—I am, etc.,

Trephine Biopsy of the Lung

Sir,—Dr. S. J. Steel and Dr. D. P. Winstanley report (1 July, p. 30) that they have not encountered any instance of air embolism in one hundred trephine biopsies of the lung.

I hope they will not allow one hundred consecutive pieces of good fortune to convince them that their technique is safe. The insertion of a cannula into the lung and the removal of its trocar can cause rapidly fatal air embolism. I have known one such case. If the technique can be modified so that the cannula is kept occluded throughout this risk may be reduced.—I am, etc.,

A. L. Jacobs.

Whittington Hospital,
London N.19.

Scopolamine with Morphine

Sir,—Dr. J. S. Crawford questioned recently (21 January, p. 172) the accuracy of a statement made in an earlier leading article (26 November 1966, p. 1282) to the effect that combinations of scopolamine with morphine in the management of labour caused more depression of respiration in the newborn than did morphine alone. Some results obtained here using the pregnant rat at term as a laboratory model are of interest in this context.

Drugs were given to the mothers by the subcutaneous route after determination of the normal rate of respiration. The frequency of maternal respiratory movement was assessed again after 30 minutes and any change expressed as a percentage of the control values. The mothers were then killed by dislocation of the neck, the young delivered by caesarean section, and five from each mother placed in the separate chambers of a respirometer, the details of which were described recently.[1] Respiratory activity of the young was expressed as oxygen consumption/100 g./minute, corrected to s.t.p. Six mothers, and therefore 30 newborn, were used to study each drug and dose combination. Some of the results obtained are summarized in the accompanying table.

Scopolamine alone at a dose level of 4 mg./kg. had negligible effect on maternal and neonatal respiration. Morphine alone at 1.25 mg./kg. did not significantly affect the maternal respiratory rate, but resulted in the young being born with a substantially reduced oxygen consumption (17.9% depression from control values). When the mothers were treated with both drugs in combination the young were no more depressed than with morphine alone, but the maternal respiratory frequency was very significantly reduced. The same pattern emerged using different dose combinations, and the effects of 0.5 mg./kg. scopolamine with 6.25 mg./kg. morphine is also shown in the table.

Effects of Morphine and Scopolamine Administered to Pregnant Rats at Term on the Respiratory Rate of the Mothers and the Rate of Oxygen Consumption of the Newborn

Drug	Mean Depression of Maternal Respiratory Rate (% Control)	Mean Depression of Neonatal O_2 Consumption (% Control)
A Scopolamine, 4·0 mg./kg. ..	0*	2·75† ± 1·91
B Morphine, 1·25 mg./kg. ..	0·48† ± 2·58	17·9 ± 2·67
A+B	16·2 ± 3·9	15·28 ± 2·64
C Scopolamine, 0·5 mg./kg. ..	0*	4·43† ± 1·00
D Morphine, 6·25 mg./kg. ..	9·4 ± 1·8	25·4 ± 1·61
C+D	42·3 ± 3·2	25·9 ± 1·16

* The means for scopolamine alone actually represent insignificant degrees of stimulation.

† Not significantly different from the relevant means for placebo-treated animals.

These results suggest that, so far as the rat is concerned, scopolamine does not potentiate the neonatal respiratory depression caused by maternally administered morphine. The projection of results from the animal pharmacology laboratory to man should be treated with caution. However, although there appears to be no recent reliable report of a clinical investigation of scopolamine–morphine combinations in the management of labour, the data presented by Flowers[2] using pethidine support the pattern observed in the rat study. The Apgar scores of infants delivered from mothers receiving scopolamine and pethidine were very clearly not different from those of infants born of mothers treated with pethidine alone.—I am, etc.,

Infant-scalp-vein Needles

Sir,—Dr. C. F. P. Wharton (10 June, p. 702) and Mr. H. F. Nagamia (1 July, p. 48) have recently reported that an infant-scalp-vein drip is superior to conventional intravenous cannulae for treatment of adults in certain clinical situations. I should like to add a further indication for the preferential use of this type of drip.

In myelosclerosis and aplastic anaemia the veins become sclerosed and thrombosed, owing to the oft-repeated venepuncture needed for regular transfusion. A stage is reached when it is almost impossible to insert a conventional cannula, so that after many unsuccessful attempts—each of which causes further venous sclerosis—the patient may be greatly distressed.

For several months I have been using an infant-scalp-vein drip for the weekly infusion of packed cells into a patient suffering from myelosclerosis. Insertion of the needle is far easier than with ordinary intravenous cannulae, so that the patient has much less discomfort and apprehension. It takes on average between three and four hours to infuse 270 ml. (½ pint) of packed cells when the hydrostatic pressure forcing the blood into the vein is increased by elevating the bottle of blood as high as possible. If a leg vein becomes obscured by oedema, secondary to congestive failure, the oedema should be removed by a diuretic the day prior to the infusion. The use of the diuretic would also prevent circulatory overload.—I am, etc.,

Is Anaesthetist Dentist's Agent?

Sir,—The annual report of the Manchester Local Dental Committee for the year ended 31 March 1967 states that a dentist was found to have broken his contract under the N.H.S. "by virtue of having charged patients an additional fee for the administration of endotracheal anaesthetics."

I must point out, as the distinction is important, that the Minister's final decision in this case conspicuously failed to state that the dentist had *charged* a fee, and therefore failed to support the executive council's contention that the anaesthetist was the agent of the dentist who had therefore in law charged these fees. Indeed, the Minister did not even mention this point, although the executive council had asked for a specific ruling on whether or not the anaesthetist is in law the agent of the dentist.

Throughout this case the Ministry was informed that I had charged these fees, and counsel for the dentist, at his appeal to a N.H.S. tribunal, pointed out that I had a legal right to charge these fees, and that I was not in law the agent of the dentist. This tribunal's findings were never published, nor were they quoted by the Minister in his final decision.

The Minister, unable to find that the dentist had charged a fee via the anaesthetist as his agent, gave it as his final decision (from which there is no appeal under the N.H.S. regulations)[1] that the dentist had broken paragraph 6(2) of his N.H.S. contract by *suggesting* a fee, for the dentist had very properly warned his patients that I might charge a fee for tracheal intubation and in each case advised the Dental Estimates Board when I had charged such a fee.

Paragraph 6(2) states: "Except as otherwise provided in the regulations, a practitioner shall not suggest, demand or accept from any patient or from any other person the payment of any fee or remuneration in respect of any treatment which he is required to give under these terms of service."

Having failed to state that the dentist had charged additional fees for endotracheal anaesthetics, and knowing from the evidence that I had, the Minister penalized the dentist for his so-called breach of contract by ordering that the fees, which he knew I had charged, should be withheld from the dentist's remuneration and returned to the patient.

I am writing this letter (as a supporter since my student days of a National Health

Service, with over 17 years' experience of the N.H.S.) because legally I have no standing in this dispute and therefore no opportunity to challenge the Minister's decision in open court—a test which it would not pass. Inside the N.H.S. the Minister has enormous powers, and that these powers should be used within the law is even more important than the details of this case. It is, however, particularly regrettable that the N.H.S. should now be the biggest single obstacle to the greater availability in the dental surgery of the most important safety factor in modern anaesthesia—tracheal intubation.

"Undoubtedly the safest method of operating in the oral cavity is under endotracheal anaesthesia. . . . But the numbers of patients are too great for such a methodical approach" according to your recent leading article on dental anaesthesia (25 February, p. 447). The numbers will not be too great when the Ministry removes the disabilities improperly imposed on the consultant anaesthetist working in the dental surgery.—I am, etc.,

Manchester. **Arnold M. Danziger.**

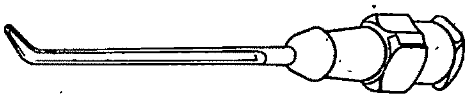
Cardiac Catheter Introducer

Sir,—I was interested in Dr. J. Mackinnon's letter (6 May, p. 377) referring to a shoehorn-type of catheter introducer for small veins or arteries. A very suitable and cheaper version can be readily made by a hospital instrument-maker from an ordinary Luer lok needle. The needle (15 to 18 gauge) is bisected along most of its length, and the short tip is bent at a right angle.



The catheter is passed along the hollowed-out tip, which occupies less of the vessel lumen than the two blades of an angled non-toothed iris forceps which I had previously used. It follows that this simple instrument is suitable for all types of vascular catheterization and need not be restricted to heart catheterization.

I claim no originality for this description, as I recently saw it used in several centres in the U.S.A.—I am, etc.,

W. G. Smith.

Shenton Park,
West Australia.

Amitriptyline and Heart Block

Sir,—That amitriptyline and nortriptyline in therapeutic doses can precipitate complete heart block is suggested by the following clinical history. Complete heart block after overdose of amitriptyline has been reported in children,[1] and has been recorded in experimental animals.[2] We have been unable to find any other reports of complete heart block following the administration of amitriptyline or nortriptyline in therapeutic doses.

A 73-year-old woman was readmitted to Wellington Hospital in April 1967 because of transient blackouts of recent onset. It was found that she was having episodes of complete heart block, alternating with sinus rhythm, and that Stokes–Adams attacks accompanied the onset of the bradycardia. Her past history included osteoporosis of the spine, mild iron-deficiency anaemia, and mental depression. In December 1966 she had commenced therapy with ferrous gluconate, calcium gluconogalactogluconate, calciferol 50,000 b.d., and nortriptyline ; the dose of the last had been increased gradually to 50 mg. t.d.s., but was reduced to 25 mg. t.d.s. because of postural hypotension. There was no past history of cardiovascular disease, and apart from an apical systolic murmur there were no abnormal cardiovascular signs during periods of sinus rhythm. Serum calcium remained normal on this regimen.

Her arrhythmia and Stokes–Adams attacks were treated with sublingual isoprenaline and oral isoprenaline hydrochloride, and her usual therapy was continued. Because of continuing Stokes–Adams attacks, all therapy was stopped and intravenous isoprenaline given. After two days there were no further Stokes–Adams attacks, nor evidence on E.C.G. monitoring of heart block, and for the next 11 days, while maintained on isoprenaline hydrochloride 15 mg. four-hourly, she remained in normal sinus rhythm. Nortriptyline 25 mg. t.d.s. was recommenced, and she continued on isoprenaline. Four days later mefenamic acid (Ponstan) was commenced for back pain. After seven days on nortriptyline further episodes of heart block with Stokes–Adams attacks were observed. Isoprenaline was increased to 45 mg. three-hourly, but attacks continued. After three days of occasional episodes of heart block it was considered possible that nortriptyline might be responsible, and it was discontinued. Stokes–Adams attacks continued for another day, but there were no episodes over the following three days. Since amitriptyline therapy was helping her depression, and its continued use was therefore desirable, it was decided to observe the response of the patient to an intravenous injection of amitriptyline (nortriptyline injections were not available). Isoprenaline 45 mg. three-hourly was continued during this time.

While resting in bed the patient was given 25 mg. amitriptyline, diluted to 20 ml., at the rate of 2.5 mg. every 2 minutes for 20 minutes. Continuous E.C.G. monitoring revealed no abnormality for the first hour after injection, but at 69 minutes post-injection complete heart block occurred without any subjective awareness. Sublingual isoprenaline rapidly reverted her to sinus rhythm, but for the next few hours there were further episodes of complete heart block; but no true Stokes–Adams attacks. By the following day, and during the next 12 days, she remained free of symptoms, nor did an hourly pulse chart reveal any evidence of bradycardia, despite a reduction in, and final withdrawal of, isoprenaline during that time.

It thus appears likely that the occurrence of complete heart block, with or without Stokes–Adams attacks, during or shortly after the cessation of two oral courses of nortriptyline, and following the intravenous administration of amitriptyline, was precipitated by those drugs.—We are, etc.,

Cervical Smears

Sir,—Like Dr. M. B. Carson (15 July, p. 177), I have been carrying out cervical smears on all my female patients between the ages of 25 and 60 years for the past 18 months.

In a relatively small series of 350 smears (out of 2,900 in a single-handed practice) I have had four patients with positive smears, all of whom have had cone-biopsies and the diagnosis of carcinoma-in-situ thus confirmed. (Incidentally, one of these patients is aged 24.)

In one of the other patients, aged 44, the cone-biopsy confirmed the diagnosis, and, there not being signs of any invasion, it was advised that she be followed up by three-monthly routine smears. When I submitted Form E.C.74 duly signed by the patient—who is fully aware of her diagnosis and the importance of having her three-monthly smears—and having indicated on the form that the patient required regular repeat smears, my claim for payment was rejected because "the patient had a smear taken in the previous five years."

This, Sir, strikes me as the most incredible of all incredible anomalies in which the Ministry of Health is so excelling. Having uncovered and treated what the test is designed to do, as soon as the test becomes an important and valuable prognostic tool it no longer attracts a fee. It is insulting enough to have to claim a ridiculous fee and to get the patient to sign—as if we were all crooks—but when the test becomes a follow-up measure then one is obviously no longer providing a service, at least not in the Minister's thinking.

What then, if I may ask, is the purpose of the test ?—I am, etc.,

London E.1. **K. E. Schopflin.**

Sir,—In relation to Dr. M. B. Carson's letter (15 July, p. 177), I can report how this regulation is carried to the bureaucratic extreme. I have just had payment refused for a smear because I carried this out precisely 17 days before the patient's 35th birthday. The age limit for smears seems particularly inappropriate in this practice, since the only two deaths from carcinoma of the cervix in the past years have been in patients in whom it was first diagnosed at the age of 33 years.—I am, etc.,

Street,
Somerset. **R. D. Last.**

Experiments on Man

Sir,—Further to my letter (8 July, p. 109) offering qualified support to Dr. M. H. Pappworth's views, as expressed in his book *Human Guinea-pigs*, it has occurred to me that the printing of the name of my hospital might be construed in some quarters as implying that "human experimentation" was, or has been, taking place there.

I would be most grateful if you would allow me to make it absolutely clear that the opinions I expressed (which I maintain) were entirely my own, and that to the very best of my knowledge and belief absolutely nothing that could be thus interpreted takes or has taken place at this hospital. I am proud and pleased to be able to say this in all honesty.—I am, etc.,

Queen Elizabeth Hospital,
Birmingham 15. **B. W. Roper.**

Appointment Systems in General Practice

SIR,—Dr. A. Smith's letter (15 July, p. 180) stressing the value of the doctor-patient relationship is surely an argument against rather than for the appointment system in general practice. I like to regard my patients as personal friends coming in for a chat (incidentally involving diagnosis and supervision of treatment) rather than as clients for whom an appointment has to be arranged. If Dr. Smith's patients are prepared to wait three days to see him, what is so harmful about the occasional half-hour in the waiting-room?

Even the hardest-worked general practitioner can eliminate a crowded surgery by dint of a little extra effort—for example, by starting half-an-hour before the scheduled time. Then there is the therapeutic value of the waiting-room milieu itself. Many a person has found the most beneficial part of a visit to the doctor to be the opportunity of "comparing notes" with other sufferers in the surgery. There are all too few places to-day where people can congregate and talk, with the immense benefit this simple exercise brings them. Do not let us too readily squeeze sensitive and often lonely human beings into units which fit into our preconceived notions of efficiency. By doing so much of a general practitioner's effectiveness is lost.—I am, etc.,

S. L. HENDERSON SMITH.

Huddersfield,
Yorks.

Repeat Prescription Cards

SIR,—Following the publication of my paper "Appointment Systems in General Practice. How Patients Use Them" (24 June, p. 827) I have received so many requests from doctors asking for details of the repeat prescription card which we use in our practice that I find it impossible to send each of them a specimen.

It is a stiff, folded card measuring 11.5 cm. × 7.5 cm. and has printed on the outside:

KEEP CAREFULLY

To get a repeat Prescription without seeing the Doctor leave this card at the surgery in an unsealed, self-addressed envelope and collect your Prescription the following day.

If you stamp your envelope it will be posted to you.

The doctor's name and address are on the back, and inside on the left is space for the patient's name and address, the prescription or prescriptions, and a short description of each drug. The right side is headed "Dates of Renewal."

I hope this description will help interested practitioners.—I am, etc.,

J. S. K. STEVENSON.

Stevenston,
Ayrshire.

Merit Awards to Hospital Staff

SIR,—There is no doubt that Mr. C. Remington-Hobbs (1 July, p. 52) is coming to the heart of the objections to present assessments in the N.H.S. when he refers to the need for complete openness and objective assessment. In certain fields a reasonable statistical analysis would probably be helpful to throw light on better modes of treatment in any case. A concrete suggestion from me regarding this for psychiatry was printed in the *B.M.J.* (3 April, 1965, p. 923). Unfortunately there seemed to be very little interest in an attempt at more objectivity at that time.

There seem to be strong feelings throughout the country that genuinely objective assessments often do not occur. Thus it is felt that, notwithstanding Mr. Remington-Hobbs's categories of research work and so on, these factors may be ignored under personal pressures. The feeling appears to be that what counts is whether one is in or out of favour with members of the "in group" (often with London or teaching hospital connexions). Thus it may be felt that support from people of the greatest experience and integrity, indeed from large numbers of doctors, is cast aside if these people are not powerful members or connected with this "in group." Startling contradictions seem to be solved not by candid examination of documents and background but by a rubber-stamping of the powerful "in group's" wishes.

These feelings would be dispelled as unjust suspicions by awkward, unworthy characters, etc., if there was genuine openness. One can see no reason for the present Star Chamber approach. If there are startling conflicts based not on fact but on opinion or alleged facts never brought to the light of day then reasonable unease will continue. Truth does not need to be hidden or to work in the dark, and one must agree with G.P.s, who on the whole seem to be both fair and sensible about what often goes on regarding merit awards and the like.—I am, etc.,

Colchester, Essex. HARRY JACOBS.

Form E.C. 73

SIR,—I would like to draw your attention to the "accident" aspect of this form. I find that though the Council were glad to receive the record of my injection they are not willing to pay for a tetanus toxoid injection—given along with A.T.S. as emergency treatment to a patient on another physician's list.

This strikes me as an omission that should be rectified.—I am, etc.,

A. B. LEYS.

Bo'ness,
West Lothian.

Opportunities in British Medicine

SIR,—The Ministry of Health is to send an interview board to persuade British graduates in U.S.A. and Canada to return to this country (15 July, p. 128). Why wait until these doctors have left Britain? Why not interview applicants for immigrant visas and surprise them with information on the career opportunities mentioned in the Ministry's advertisement? This step may save a few return fares to the United Kingdom. Or, at second best, the interview board might inquire why the prospective immigrants are leaving the country, and, making use of this information, make recommendations on career structures and conditions of service in this country.

When I worked in the U.S.A. I met some British doctors who were there because they had found it almost impossible to make use of their skills in Britain. Their prospects had seemed poor when they left Britain, and time and distance had not improved the view. However, the interview board may well have a vision which is not apparent to most of us here.—I am, etc.,

Edinburgh 12. P. D. ROBERTSON.

Points from Letters

Indomethacin and Duodenal Ulcer

Dr. D. G. EMERY (Selly Oak, Birmingham) writes: I thought it would be interesting to report that in one patient with a known duodenal ulcer the use of indomethacin suppositories resulted in an increase in his gastric symptoms. The condition was so marked that he had dyspeptic symptoms only on the day after using a suppository the previous evening. His symptoms were controlled by increasing his antacids.

Neurotoxic Effects of Piperazine

Dr. W. E. BEER (Caernarvonshire and Anglesey General Hospital, Bangor) writes: I was most interested to read Dr. D. C. L. Savage's letter (24 June, p. 840). I recall a similar case. A young woman was being treated with piperazine citrate for threadworms. Dosage was within the recommended range. She was considerably alarmed to find that while combing her hair, picking up an object, or opening a door her hand would at times jerk off course. She happened to be on tetracycline at the same time for another condition, and I wondered if it was the combination of therapy that was somehow responsible or if it was the piperazine. In view of the experience of Dr. Savage's case, piperazine would appear to be responsible. The condition cleared on discontinuation of both drugs.

Too Easy to Forge?

Dr. M. D. RIPKA (London N.W.1) writes: Under the heading "Too Easy to Forge?" (24 June, p. 852) your legal correspondent refers to prescription forms supplied to doctors by the London Executive Council as having been criticized at London Sessions for being in a form likely to facilitate forgery. The Chairman of the Inner London Sessions Appeal Committee is reported to have said: "I hope in future that the London Executive Council will take it into their heads not to issue prescription forms with the name of the doctor stamped on them." The Chairman should be enlightened that the stamping of a doctor's name on prescription forms is most helpful to the pharmacist actually catching a forger, as he is thereby able to contact the doctor concerned if he has any suspicions about a prescription. . . . In the past, before the doctor's name was stamped on his prescription form, it was often impossible for the pharmacist to decipher the doctor's signature and effect any checking he desired to do. . . . Apart from investigating possible forgeries it is a great help when queries arise—for instance, those caused by unavailability of drugs, or inability to decipher items prescribed.

Intestinal Obstruction by Food

Miss D. E. O'DOHERTY (Sutton, Surrey) writes: Your leading article (24 June, p. 782) about unusual foods causing intestinal obstruction recalled to me a case I had several years ago of an elderly woman sent into the local hospital as an emergency.

She was extremely emaciated and suggested a late stage of carcinoma. She was acutely obstructed and at laparotomy I found a smooth ovoid mass about the size of a pigeon's egg impacted in the lower ileum. This was removed without great difficulty, and on closer examination proved to be a closely packed mass of fibrous material. On teasing this out the material filled a fair-sized kidney dish, and looked to me like grated coconut fibre.

On inquiry later the patient confessed to a great liking for coconuts and admitted to eating a whole one a few days previously. She made a good recovery.

Obituary Notices

Sir EARDLEY HOLLAND, LL.D., M.D., F.R.C.P., F.R.C.S., F.R.C.O.G.

Sir Eardley Holland, a former president of the Royal College of Obstetricians and Gynaecologists, and consulting obstetrician and gynaecologist to the London Hospital, died at his home in West Dean, Chichester, on 21 July. He was 87.

Hay Wrightson

Eardley Lancelot Holland was born on 29 October 1879, the son of W. Lancelot Holland, of Puttenham, Surrey. His mother was the daughter of Canon Eardley-Wilmot. He was educated at Merchiston Castle School, Edinburgh, and then came south to King's College, London. He took his medical training at King's College Hospital, then near the Strand, qualifying with the Conjoint diploma in 1903, and graduating M.B., B.S. with first-class honours in medicine in 1905. He took his Fellowship of the Royal College of Surgeons in the same year, and in 1907 proceeded M.D., and was awarded the gold medal for midwifery and diseases of women. The Fellowship of the Royal College of Physicians came later, in 1920, and that of the Royal College of Obstetricians and Gynaecologists on its foundation in 1929. After holding early hospital appointments he undertook further study at the University of Berlin, and on his return to England was for a time resident medical officer at Queen Charlotte's Maternity Hospital, and at the Hospital for Women, Soho Square. From 1907 to 1916 he was assistant obstetric surgeon at King's College Hospital, and also, during the whole of that period except for the last two years, tutor in obstetrics. From 1907 to 1916 he was also gynaecological surgeon to the Metropolitan Hospital. In 1916 he obtained his appointment as obstetric and gynaecological surgeon to the London Hospital, of which another bearer of the family name of Holland, the late Lord Knutsford, was the vigorous chairman. He retained that appointment until 1946, when he retired to an honorary consulting position. The first world war broke in upon his early career at the London, and he served as temporary captain in the R.A.M.C., being employed as surgeon specialist in France, in charge of No. 20 General Hospital. During the second world war his task was a very different one; he was in charge of the maternity services of the Ministry of Health on behalf of London women evacuated into Hertfordshire from 1939 to 1943. Other hospital appointments which he held were those of consulting obstetric surgeon to the City of London Maternity Hospital, and gynaecologist to the Florence Nightingale Hospital.

A man of many activities, in addition to a large private practice, he seemed to have a hand in all the developments affecting his own branch of medicine, and much beyond it. One of his actions on becoming president of the Royal College of Obstetricians and Gynaecologists in 1943 was to set up a strong committee to review the many deficiencies in the maternity services of that time, and to impress the views of obstetricians on those concerned. The aim of the committee was to modify the National Health Service Bill, then under discussion. The report of the committee, published in 1944, was a comprehensive review of the whole subject, including the social and economic factors concerned. The British Medical Association took exception to some remarks in the report about general practitioners which seemed to suggest a desire to exclude the general practitioner from midwifery practice. Eardley Holland was violently opposed to the term "general-practitioner obstetrician" which, he said, was an absolute sham and a misuse of the word "obstetrician." He remarked how few individual obstetricians could gain a real insight into the causation of maternal mortality because they saw relatively so few deaths. He himself, he said, did not gain such an insight until the beginning of the second world war, when it became one of his duties to investigate every maternal death in the Home Counties. The commonest cause he found to be shock or haemorrhage, or both.

Holland was a member of the Central Midwives Board; editor of the *Journal of Obstetrics and Gynaecology of the British Empire*; a member of the Board of Advanced Medical Studies of London University; and examiner in midwifery and diseases of women to the universities of Cambridge, London, and Durham, the Royal College of Surgeons of England, and the Central Midwives Board. He was the obvious president for the 12th British Congress of Obstetrics and Gynaecology held in London in 1949. Two years later he delivered the William Meredith Fletcher Shaw Memorial Lecture before the Royal College of Obstetricians and Gynaecologists, taking for his subject "The Princess Charlotte of Wales: A Triple Obstetric Tragedy." He was also a member of the General Council of King Edward's Hospital Fund for London, where he interested himself particularly in the provision of radium for the treatment of cancer. He was on a number of committees of the British Medical Association, among them the Medical Planning Committee and the Consultants and Specialists Committee, and was a representative at the Annual Meeting of the B.M.A. in 1943–4.

A writer of clarity and precision, the outstanding literary work with which his name is associated is the *Manual of Midwifery*, in which he collaborated with Dr. T. Watts Eden, and which ran through many editions. Later he became its sole author, and several further editions were brought out under the title of Eden and Holland's *Manual of Obstetrics*. He acted as chairman of a subcommittee of the Ministry of Health, which produced a report in 1922 on the causation of foetal death. In 1933, together with R. C. Jewesbury and Wilfrid Sheldon, he wrote *A Doctor to a Mother: the Management of Maternal and Infant Welfare*; and later, with Dr. Janet Lane-Claypon (later Lady Forber—see obituary below), he published a child-life investigation, involving a study of 1,673 stillbirths and neonatal deaths. To Eden's *System of Gynaecology* he contributed an article on hernia in women, and he wrote much else, mostly in the form of papers in the professional and scientific journals. He was editor of *British Obstetric Practice*, which appeared in 1955 and ran through further editions.

His name was widely known throughout the world in the field of obstetrics and gynaecology. He was an honorary Fellow of the Royal Society of Medicine, and of the American, French, German, and Brazilian gynaecological societies, and of the Royal Medical Society of Budapest. He was honorary M.D. of Dublin, honorary LL.D. of Birmingham and of Leeds, honorary Fellow of the Royal College of Surgeons of Edinburgh, and honorary Master of Midwifery of the Society of Apothecaries of London. He was knighted in 1946.

He married, firstly, in 1913, Dorothy Marion, daughter of Mr. Henry Colgate, F.R.C.S., of Eastbourne. She died in 1951, and in 1952 he married Olivia, daughter of Mr. Leslie Constable, J.P., of Fittleworth, Sussex. By his first marriage he had three daughters.

J. H. P. writes: The death of Eardley Holland marks the end of an era in the history of obstetrics and gynaecology in this country. He was almost the last survivor of that small band of gynaecologists who, under the leadership of Blair-Bell, had founded the Gynaecological Visiting Society of Great Britain and Ireland. Eardley Holland took an active part in the deliberations within the society which ultimately led to the foundation of the College of Obstetricians and Gynaecologists. He was not only a founder Fellow but he was co-opted to the first council which was formed in 1929, and became honorary treasurer of the College the following year. He played, therefore, a vital part in stabilizing the finances of the College in its first years. When he relinquished the honorary treasurership he was elected vice-president, and became president in 1943. It was during his presidency that the first of a series of reports on a national maternity service was published. This report was of particular importance in view of the impending National Health Service. Although a staunch believer in the College of Obstetricians and Gynaecologists, he favoured the closest co-operation with the other colleges, and it was during his presidency that agreement was reached between the Royal College of Surgeons and the Royal College of Obstetricians and Gynaecologists, whereby each had a representative on the council of the other.

Eardley Holland's undergraduate medical education was, like that of Blair-Bell, at King's College Hospital. After graduating he worked for a time in Germany. Throughout the whole of his life he remained a firm admirer of the German school of gynaecologists, and from among them he had many close personal friends. He was always deeply distressed that he should have had to live through two wars involving a country with which he had so many close personal ties. After an outstandingly brilliant undergraduate and postgraduate career it was not surprising that he should have been appointed to the staff of King's when a vacancy occurred in 1914. This was just after that hospital had moved to its present site on Denmark Hill. This fact, together with the outbreak of the first world war, interfered with the development of the hospital at that stage, and Eardley Holland accepted an invitation to join the staff of the London Hospital, where there were far better facilities at that time for both clinical research and practice. It was from that department that he soon produced his classic paper on stillbirths, and went on to develop a deep and lasting interest in regard to the country's maternity services. The social aspects of midwifery occupied a prominent place in his work, in his thinking, and in his writings. The latter were very numerous. Eden and Holland's textbook was as much a necessity for one generation of undergraduates as *British Obstetric Practice*—which he edited after his retirement—became to a later generation of postgraduates.

Eardley Holland was possessed of a very imposing physical appearance, upright and grand, almost haughty, yet he was always courteous and considerate. Quite often he was irascible, but more often kindly and gentle. He was a man with very firm likes and dislikes, who never hesitated to speak his mind whether it was to bestow praise or to administer a reprimand. Like all outstanding leaders he displayed great interest in the younger generation. My memory of meeting for the first time this rather awe-inspiring person, when a young man on the threshold of my career, is of being greeted with encouragement and praise for what, in retrospect, was an endeavour of little merit.

Personalities seem to be disappearing from the contemporary medical scene, but personality was something Eardley never lacked. Anyone with such forthright and freely expressed opinions inevitably had a few detractors, but they were vastly outnumbered by his admirers. Obstetrics and gynaecology owe a very great debt to this man, who worked throughout his lifetime to improve the maternity services of this country, whether it was in his own hospital department or through the activities of the Royal College. He derived great satisfaction from the improvements which took place during his lifetime.

Lady FORBER, D.SC., M.D.

Lady Forber (née Lane-Claypon), a former dean of King's College for Women (now Queen Elizabeth College), London, died on 17 July at Seaford, Sussex. She was 90.

Janet Elizabeth Lane-Claypon was born in Boston, Lincolnshire, on 3 February 1877, and entered University College, London, graduating B.Sc. with first-class honours in physiology in 1902, and taking the D.Sc. in 1905. She had a distinguished student career, and in addition to being a university scholar and gold medallist she held a B.M.A. research scholarship in 1902–3. For her clinical studies she entered the London School of Medicine (now the Royal Free Hospital), graduating M.B., B.S. in 1907. After holding several hospital appointments she proceeded M.D. in 1910. In that year she was appointed lecturer in physiology and hygiene at Battersea Polytechnic and in 1912 at King's College for Women. From then till 1916 she was an assistant medical inspector to the Local Government Board. In 1916 she became dean and lecturer in hygiene at King's College for Women, a post she held until 1923. In 1920 she was appointed a magistrate. She married in 1929, as his second wife, Sir Edward Rodolph Forber, who died in 1960.

A friend writes: One of the earliest acts of the Medical Research Committee—the Medical Research Council's immediate predecessor—was to commission Dr. Janet Lane-Claypon to write a book on *Milk and its Hygienic Relations*, which appeared in 1916. She later assisted in the preparation, jointly with Dr. (later Sir) Eardley Holland, of a report of the Medical Research Council's Committee on antenatal and postnatal problems of child life, which was published in the Council's Special Report Series in 1926. During the time Dr. Lane-Claypon was dean at King's College for Women she actively encouraged research in the departments under her control, and from time to time would approach the M.R.C. in support of applications from research workers there.

E. NEUMARK, M.D., M.C.PATH.

Dr. E. Neumark, lecturer in pathology at St. Mary's Hospital Medical School, London, died suddenly on 12 July. He was 55.

Ernst Neumark was born in Germany on 20 September 1911, and came to Britain as a refugee at the age of 22. He received his medical education at University College Hospital, London, qualifying with the Conjoint diploma in 1939. After hospital appointments he joined the pathology department of St. Mary's Hospital Medical School in 1943, and there he remained until his death. In 1947 he graduated M.B., B.S. and became a naturalized British subject in the same year. He proceeded M.D. in 1949, and in 1963 became a member of the College of Pathologists.

D. M. P. writes: The sudden death of Ernst Neumark removes from haematology one of its best-known personalities. He attended regularly at conferences and was a prolific writer (in four languages). Among other things, he translated, and with C. J. C. Britton was the co-editor of, Leitner's *Bone Marrow Biopsy*. He also contributed to Savill's *System of Clinical Medicine*. His most recent work concerned the influence of external temperature on the distribution of fatty marrow. But perhaps his most important contribution was in introducing to English pathology Di Guglielmo's disease. For many years he was medical adviser to the Haemophilia Society, and he took an active part in the formation of the World Federation of Haemophilia. In 1960 he visited many European laboratories, especially in Italy, where he was made an honorary member of the Società Internazionale di Ematologia. It was, however, as organizing secretary of the seventh European Congress of Haematology in London in 1959 that he became so well known personally. Nothing was too much trouble in attending to the needs of delegates, and his assiduity went far to making this particular congress such a success. The many friendships he formed were fostered by the hospitality provided in his home.

Ernst Neumark loved lecturing and demonstrating and organizing clinicopathological conferences. He will be remembered with affection by many generations of students, and by all his pathology colleagues, many of whom have gone to senior appointments elsewhere. It cannot be said that his clinical colleagues always found him easy—his interests were too numerous and his character too volatile for steady clinical rapport—but they also will remember him with affection. There can be no denying the enthusiasm he had for his work, and especially for the great occasions. He was a splendid showman, and the excellent state of the museum at St. Mary's could stand as his memorial.

A man of obvious culture, he was a good companion, and his skill on the accordion could make a party hilarious. He could be obstinate in his opinions, right or wrong, but was steadfast in his loyalties—a good Jew, devoted husband, and loving father.

Sir CLAUDE FRANKAU, C.B.E.
D.S.O., M.S., F.R.C.S.

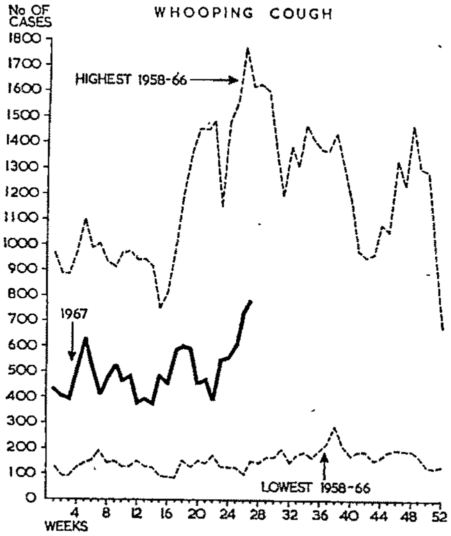
C. F. M. writes: When I first met Claude Frankau (obituary, 8 July, p. 116) he was surgical registrar at St. George's and gave a lot of his time to teaching and encouraging his juniors and students. In due course he was appointed assistant surgeon, and I believe he held the record for the length of time he bore this status before rising to that of full surgeon, owing to the relative youth of his seniors. This fact, however, did not prevent him from establishing an extensive private practice, for he was held in great esteem because of his diagnostic acumen and technical skill. He had a decisive manner which inspired confidence in both colleagues and patients. Through the years he served his country and St. George's with unflagging energy, and those who had the benefit of his teaching will never forget the patience, humour, and enthusiasm with which he passed on his knowledge. He could be witheringly caustic on occasion, but no one resented a blistering from him, as it was always deserved and taught a lasting lesson. As a surgeon he had all the skills: dexterity, gentleness, judgement, and the knowledge to put them to the best use. As a man and a friend he was everything which is implied by these terms at their best. His example has inspired many who hold illustrious positions in the surgical world of today.

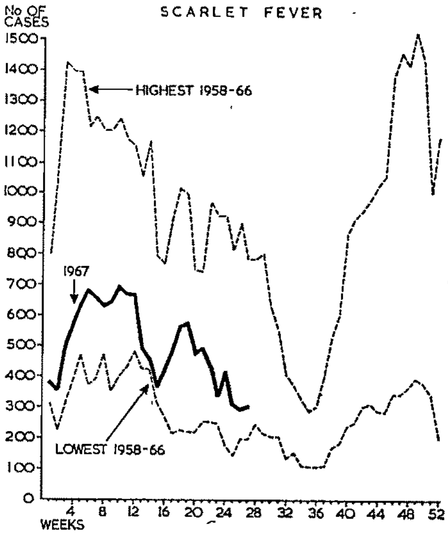
News and Notes

EPIDEMIOLOGY

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of whooping-cough and scarlet fever in England and Wales. Figures for 1967 are compared with the highest and lowest figures for each week in the previous years shown.





Infectious Diseases

Areas where numbers of notifications were high in the latest two weeks for which figures are available.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending 8 July (No. 27) and corresponding week 1966.

Figures of *cases* are for the countries shown and for Greater London. Figures of *deaths* and *births* are for the whole of England and Wales (London included), Greater London, the 17 principal towns in Scotland, the 10 principal towns in Notrhern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

PARLIAMENT

Abortion Bill Under Fire in the Lords

[FROM OUR PARLIAMENTARY CORRESPONDENT]

Even the title of the abortion law reform Bill has come into question since the measure left the Commons and went to the Lords for second reading on 19 July. The Bill, Medical Termination of Pregnancy, got through this stage by 127 votes to 61, but it was subjected to some rough handling, presaging a contentious committee stage on 26 July. The third reading will not take place until the end of October, when Parliament resumes after the summer recess for a few days' "spill over" session to dispose of outstanding business before the 1967–8 session begins.

LORD SILKIN, sponsoring a measure of this kind for the third time since November 1965, said the Bill had been considerably emasculated in the Commons. It embodied a number of compromises, and he thought it could have been accepted in its present form by even its strongest opponents as reasonable and fair. It appeared that "the more one throws to the wolves the hungrier they become."

The **ARCHBISHOP OF CANTERBURY** said he very much wanted to see reform of the law on abortion, but the Bill contained some very bad features, and unless it was amended he could not support it. It would be possible to omit the reference to the existing children of the family—"the social clause coming in again through the back door"—and to move the provision about the substantial risk of the birth of a handicapped child and make it part of the provision about the mother's total environment. With these amendments the Bill would make the mother's life and health the sole matter for diagnosis by the doctor and the sole ground for abortion.

Non-medical Reasons

LORD BROCK, speaking as a surgeon, said the amendments made to the Bill had satisfied many doctors, and some medical bodies, that the main basis for abortion was medical. It was against the ethics of most surgeons, he said, to take part in abortion for non-medical reasons. While many had been prepared to go a long way in stretching the medical criteria as far as they could, there was a limit to what could be expected. Many surgeons were uneasy and felt that even now the boundaries of medical indication for termination of pregnancy had been overstepped, and that the implementation of the Bill would disregard them. "I must make it quite clear," he said, "that, although some surgeons will agree to do operations for non-medical reasons, most will refuse to do so, and their resolution has hardened as a result of the pressures put upon them." Many fears would be allayed, he added, if the phrase "any existing children of her family" were removed.

He objected to the title of the Bill. It was loose, vague, and open to misrepresentation. As he saw it, the meaning intended was the termination of pregnancy for medical reasons. Such a title would be simple, direct, and clear. He suspected the real reason behind the present title was just "legal abortion." The word "medical" was used in an attempt to make abortion more acceptable.

Criticizing Clause 4, the conscience clause, he said he felt that no doctor, and certainly no surgeon, should have to explain or justify a statement that it was against his will to do an operation for non-ethical reasons, and least of all should he be compelled to prove it in a court of law.

The Bill should contain definite indications that it recognized it would be unethical for a doctor to do operations against the tenets, morals, or conscience of his profession.

Approved Experience

LADY SUMMERSKILL, after some reflections on the failure of the Government to accept responsibility for so important a social change, pointed to a serious omission in the Bill. Clause I provided for a pregnancy to be terminated on the opinion of two registered medical practitioners, but it did not specify that one of them should be a doctor approved for the purpose. Why go to the length of providing an adequate and proper place for an operation, she asked, if you are not going to provide an adequate and proper person to do it? An approved register or list of doctors permitted to provide special services was not new. If it was found that a doctor on the approved list abused his position he could be removed. That did not mean he would be struck off the *Register*.

LORD AMULREE, on the other hand, was pleased that the Bill did not restrict the type of doctor who could perform an abortion. It did in a sense do so by the provision that the operation must be in a National Health Service hospital. That must mean there was some choice about the type of doctor who was to do it.

If the real purpose of the Bill when it started was to convert case law into statute law he was uncertain about the phrases "any existing children of her family" and "the patient's total environment actual or reasonably foreseeable" and the conscience clause.

Illegal Abortions

LORD PLATT wanted to know what were social and medical reasons. Even if the apparently offending phrases were interpreted as being a social rather than a medical provision, surely doctors for centuries had taken into account the social conditions of their patients. He had always taught his students that they did not understand the full implications of a case unless they had taken into account the social state in which the patient lived, and every other relevant consideration.

He hoped that those who were inclined to talk about the sanctity of human life would remember the 50,000 to 100,000 human foetuses which were being destroyed annually in conditions of squalor or dreadful extravagance. He would not be in favour of a grossly emasculated Bill that would leave them with the status quo and do nothing to lessen the number of illegal abortions.

LORD SEGAL could extend only a tepid welcome to the Bill, which in his view was badly in need of amending. He welcomed the conscience clause, by which a doctor was enabled to opt out of performing an operation to which he had a conscientious objection.

Treatment Centres for Drug Addicts

It was stated on behalf of the Government in the House of Lords on 19 July that so far there are 10 hospitals in London providing inpatient treatment for heroin addiction and 13 outpatient treatment. At six of the latter a service is available in the casualty department 24 hours a day, at three others there is a service five days a week, and at the remaining four facilities are available less frequently. At most of these hospitals staff are not exclusively concerned with the treatment of addicts. At Birmingham inpatient and outpatient treatment is provided at All Saints' Hospital, where the outpatient department is open from Monday to Friday, 8.30 a.m. to 6 p.m. In the rest of the country inpatient and outpatient treatment is available if required in most psychiatric hospitals.

Services in the London area, where the main concentration of addicts is believed to be, are still being developed, and it would be premature, and against the interests of addicts generally, to publicize the names of hospitals at present. General practitioners in the areas concerned are made aware of the services as they become available.

Bills Passed

The Sexual Offences (No. 2) Bill, permitting homosexual acts between consenting adults in private, was given the third reading in the House of Lords on 21 July.

The Dangerous Drugs Bill, with a new clause increasing from 2 to 10 years the maximum period of imprisonment for smuggling drugs, was read the third time in the House of Lords on 21 July.

Emigration of Doctors

Dr. **DAVID KERR** (Wandsworth Central, Lab.) asked the Minister of Health on 24 July for a statement on his study of emigration and immigration of doctors.

Mr. **ROBINSON**: "An analysis of information available from the Central Index of doctors maintained by the Health Departments and the British Medical Association about doctors entering and leaving Great Britain during the two years from 30 September 1962 to 30 September 1964 has now been completed. The results indicate a net loss of about 300 British- and Irish-born doctors a year, a figure well below some earlier estimates, balanced by a gain of roughly the same number of doctors born elsewhere. Details will be published shortly, and work on similar analyses for later years is proceeding."

MEDICAL NEWS

Royal Society of Medicine

At the annual meeting of the Royal Society of Medicine held on 18 July the following fellows were elected officers for 1967–8: *president,* Sir **HECTOR MACLENNAN** ; *honorary secretaries,* Dr. **G. E. W. WOLSTENHOLME** and Mr. **R. S. HANDLEY** ; *honorary treasurers,* Mr. **MYLES L. FORMBY** and Dr. **W. D. WYLIE**.

Honorary Professorship

The title of honorary professor has been conferred on Dr. **W. M. COURT BROWN** by the University of Edinburgh. Dr. Court Brown is director of the Medical Research Council's Clinical Effects of Radiation Research Unit at the Western General Hospital, Edinburgh, a post held since 1956. He joined the scientific staff of the Council in 1950 and from 1950 to 1956 he worked in the department of medicine at the then Postgraduate Medical School of London. During this early period he was specially concerned with studying the late harmful effects of radiation exposure to man, and with Dr. **RICHARD DOLL**, F.R.S., of the Council's Statistical Research Unit, he investigated the nature of the dose-effect relationship for the radiation induction of leukaemia in man. Since 1956 Dr. Court Brown has become increasingly interested in various aspects of human cytogenetics, in particular with the development of population cytogenetics, in the clinical significance of chromosome aberrations, and in radiation cytogenetics.

R.C.S.I. Appointment

Dr. **ALAN D. H. BROWNE** has been appointed professor of obstetrics and gynaecology at the Royal College of Surgeons in Ireland. He graduated from Trinity College, Dublin, in 1947, and after a period of training in Dublin and Manchester he returned as assistant master of the Rotunda in 1951. He was consultant gynaecologist to Dr. Steevens's Hospital and Drumcondra Hospital, Dublin, from 1955 until his appointment as master of the Rotunda Hospital in 1960. Dr. Browne is a Fellow of the Royal College of Physicians in Ireland and of the Royal College of Obstetricians and Gynaecologists. He holds the M.D. of Dublin University.

Cancer Registration

A supplement to the Registrar General's statistical review for 1961 contains data derived from the National Cancer Registration Scheme (see *B.M.J.*, 1964, 1 August, p. 265). Of 111,613 patients registered in 1961 56,829 (51%) were male and 54,784 (49%) were female. Among males the commonest forms of cancer were lung cancer (29%), cancer of the stomach (10%), and rodent ulcer (8%) ; among females cancer of the breast (24%), cancer of the large bowel (13%), and cancer of the womb (12%). The registration rate for all forms of cancer was higher in urban areas (2.5 per thousand population) than in rural areas (2.2). Of 46,385 cases of cancer in males registered in urban areas 30% were of lung cancer ; in rural areas 23% of the 10,444 cases registered related to this condition. The report gives survival analyses for a number of specific sites. (*Registrar General's Statistical Review for the year 1961, Supplement on Cancer,* H.M.S.O., 7s. 6d. net.)

Hospital Building in 1960s

Opening a new ward block at St. Albans City Hospital on 18 July, the Minister of Health, Mr. **KENNETH ROBINSON**, gave figures to show the accelerating pace of hospital building. In the five years ending September 1966, he said, building schemes to the value of £223m. were completed, representing well over half the total for the entire period of the National Health Service. The value of schemes in progress at the end of September last was £234m. New work to the value of £122m. was expected to be started during the current financial year.

Danger of Lead Poisoning

A warning was sent last week by Sir **GEORGE GODBER**, Chief Medical Officer, Ministry of Health, to medical officers of health in England and Wales stressing the need to guard against lead poisoning from battery casings used as fuel. In his letter Sir George refers to the incident in Bradford recently reported in the *B.M.J.* (1 July, p. 56) and to another in Rotherham in 1954, when two children died and many others were affected. He points out that plants may be found to contain lead where they have been grown on soil with a high lead content and that this could occur where battery casings have been buried at an insufficient depth or when ash from the burning of battery casings has been deposited in a garden.

Age of Consent

The Committee on the Age of Majority, appointed by the Lord Chancellor under the chairmanship of Mr. **JUSTICE LATEY**, reported last week. Its terms of reference were "to consider whether any changes are desirable in the law relating to contracts made by persons under 21 and to their power to hold and dispose of property, and in the law relating to marriage by such persons and to the power to make them wards of court."

Though consent to medical treatment was not specifically named, the committee felt qualified to recommend that consent at 16 should be established. In reaching this conclusion it found support in the B.M.A.'s memorandum of evidence, which stated that consent by a person of 16 or upwards who appeared to the doctor to be capable of understanding what was involved and of expressing his own wishes should be considered valid without confirmation by his parent or guardian (see *Supplement,* 30 April 1966, p. 119). It also noted that the practice of accepting consent at 16 had proved satisfactory. Nevertheless, the committee is strongly of the opinion that the doctor, "for reasons of ethics and prudence," should make contact with the parents of a minor (or the husband in the case of a woman) unless the minor refuses permission. In its view, if the age of consent is to be lowered, it becomes more than ever essential that the nature and extent of the proposed treatment should be explained to the patient by a *medical practitioner* (committee's italics), and that it should be stated on the consent form, and signed by the practitioner, that this has been done.

The committee recommends that young people should be free to give their blood at 18. It also recommtnds that they should be free to marry at this age without the consent of their parents or of the courts. (This accords with Council's choice of age in its memorandum.) Two dissenting members of the committee considered that society was justified in "leaning against" young marriage and recommended that parental or court consent to marry should continue to be necessary until the age of 21. (*Report of the Committee on the Age of Majority,* Cmnd. 3342, H.M.S.O., 15s. net.)

Society of Apothecaries of London

At a soirée held on 18 July the Master of the Society of Apothecaries of London, Mr. **HAROLD EDWARDS**, on behalf of the court, bestowed the Society's Gold Medal in Therapeutics for 1967 on Sir **PETER MEDAWAR**, F.R.S., in recognition of his eminence in the field of experimental medicine.

Sir Arthur Porritt

Sir **ARTHUR PORRITT**, Governor-General and Commander-in-Chief (designate) of New Zealand, has had the G.C.M.G. conferred on him.

People in the News

▶ Dr. **D. G. WALKER** has been appointed by the British Postgraduate Medical Federation to the post of part-time regional adviser in dental surgery for the four metropolitan and Wessex hospital regions from 1 October.

▶ Dr. **I. G. W. PICKERING**, Director of Prison Medical Services, has been appointed a member of the Prisons Board.

▶ Dr. **R. FRASER MACKENZIE** has been appointed medical officer, Eastern Region, British Railways.

▶ Dr. **KENNETH W. NEWELL** has been appointed director of a new W.H.O. division of epidemiology and communications science.

▶ **D. B. CLAYSON**, Ph.D., of Leeds University, has been awarded the title of professor in the department of experimental pathology and cancer research.

News in Brief

St. Christopher's Hospice, Sydenham, was opened by **PRINCESS ALEXANDRA** on 24 July. An account of the aims of the hospice was published in the issue of 15 July (p. 169).

PRINCESS ALICE, COUNTESS OF ATHLONE, formally opened this week a rehabilitation unit at Finchley Convalescent Home, London N., which admits patients from the National Hospital, Queen Square, and Maida Vale Hospital.

Grants and Awards

Research grants to Glasgow University include £32,500 (£6,500 a year for five years) from the Medical Research Council for research in the department of medicine, Western Infirmary, on iron and porphyrin metabolism and lead poisoning; £12,176 from the Nuffield Provincial Hospitals Trust to develop computer techniques in medical cardiology; and £35,000 from the Wellcome Trust towards the cost of a unit for cell culture in the department of biochemistry.

Grants totalling £9,433 have been made in the first series of Kodak awards (see *B.M.J.*, 4 March, p. 579). The largest (£3,000) will support research into stress in children separated from their mothers.

Coming Events

British Industrial Biological Research Association and Society of Chemical Industry (Food Group).—Symposium, "Current Developments in Food Manufacture and Food Safety Evaluations," 20 September, 2.30 p.m., School of Pharmacy, London W.C.1.

Birmingham and Midland Eye Hospital.—Postgraduate course in industrial ophthalmology, 2–6 October. Details from Secretary, Industrial Ophthalmology Course, Research Department, Birmingham and Midland Eye Hospital, Church Street, Birmingham 3.

Societies and Lectures

For attending lectures marked ● a fee is charged or a ticket is required. Applications should be made first to the institution concerned.

Wednesday, 2 August

STOKE MANDEVILLE HOSPITAL.—12.15 p.m., Professor J. Chassar Moir: History of the Obstetric Forceps

Friday, 4 August

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. K. M. Citron: clinical demonstration.

Appointments

BIRMINGHAM REGIONAL HOSPITAL BOARD.— B. T. O'Connor, M.S., M.Ch.Orth., F.R.C.S., F.R.A.C.S, (whole-time consultant orthopaedic surgeon and director of clinical studies to the Robert Jones and Agnes Hunt Orthopaedic Hospital); A. M. Geddes, M.B., M.R.C.P.Ed. (whole-time consultant physician with experience in communicable diseases to the East Birmingham group); G. H. Davies, M.B., F.F.A. R.C.S. (joint appointment of maximum part-time consultant anaesthetist to the United Birmingham Hospitals and the Birmingham (Selly Oak) group); M. R. E. Dean, M.B., D.M.R.D. (whole-time consultant radiologist to the Shrewsbury group); M. L. Cox, M.B., M.R.C.O.G. (part-time consultant obstetrician and gynaecologist to the Coventry group).

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—W. F. Kerr, M.B., F.R.C.S.Ed. (consultant cardio/thoracic surgeon—main centre, Norfolk and Norwich Hospital); J. F. Pereira, M.B., F.R.C.S.Ed., D.O. (consultant ophthalmic surgeon, West Suffolk area).

HOME OFFICE.—The following medical officers have been appointed to H.M. Prisons as indicated in parentheses: B. Klassnik, M.B., D.P.M. and N. M D. Murthi, M B., D.T.M.&H., T.D.D. (Birmingham); I. P. James, M.B., M.A.N.Z.C.P., D.P.M., and M. C. Mitcheson, M.B., D.P.M. (Brixton); W. P. Hurley, M.B., D.P.M., and G. D. Stewart, L.R.C.P.&S.Ed., D.P.M. (Grendon); S. P. C. O'Reagain, M.D. (Liverpool); Freda S. Reed M.B., D.P.M. (Maidstone); Mary C. Ahearne M.B. (Manchester); B. D. Cooper, M.B., D.P.H (Parkhurst); W. A. S. Grant, M.B. (Pentonville); H. O'B. Howat, M.B. (Wakefield); A. W. Griffiths, M.R.C.S., D.P.M. (Wandsworth); M. Dafashy, M.B., D.P.M. (Wormwood Scrubs); B. K. Banerjee, M.B., D.P.M., and L. J. Glancy, M.B., D.P.M. (Risley Remand Centre).

MANCHESTER REGIONAL HOSPITAL BOARD.—N. Berlyne, M.B., M.R.C.P.Ed., D.P.M. (whole-time or maximum part-time consultant psychiatrist Oldham and District group); R. A. C. Jones, M.B., F.R.C.S. (whole-time or maximum part-time consultant neurosurgeon, Salford group); W. G. Owen, M.B., M.C.Path. (whole-time or maximum part-time consultant pathologist (with special interest in histopathology), Preston and Chorley group); J. W. Warburton, M.D., D.P.M. (whole-time or maximum part-time consultant psychiatrist, South Cheshire group); D. N. Hutchinson, M.B., Dip.Bact. (whole-time consultant bacteriologist, Preston and Chorley group and the Public Health Laboratory at Preston Royal Infirmary (joint appointment)); H. L. Goldwater, M.B., F.F.A. R.C.S., D.Obst.R.C.O.G. (whole-time or maximum part-time consultant anaesthetist, North Manchester, and the Booth Hall and Monsall groups); R. S. Phillips, M.B., F.R.C.S.Ed. (whole-time or maximum part-time consultant traumatic and orthopaedic surgeon, North Manchester group); C. S. Mellor, M.D., D.P.M. (part-time consultant psychiatrist (3 half-days weekly), Alcoholism Unit, Springfield Hospital); M. S. Shaikh, M.B., M.R.C.P.Ed. (whole-time or maximum part-time consultant physician in geriatrics, Ashton, Hyde, and Glossop group); G. Birchall, M.B., M.C.Path., D.Obst.R.C.O.G. (whole-time or maximum part-time consultant pathologist (with special interest in haematology), North Lancashire and South Westmorland group); F. P. S. Marriott, M.B., F.R.C.S.Ed. (whole-time or maximum part-time consultant surgeon, Bolton and District group).

NATIONAL HOSPITALS FOR NERVOUS DISEASES.—D. B. Ellis, M.B., F.F.A. R.C.S. (consultant anaesthetist).

NEWCASTLE REGIONAL HOSPITAL BOARD.—D. G. A. Westbury, M.B., D.P.M. (consultant in forensic psychiatry, Durham); T. Dowell, M.B., F.F.A. R.C.S. (consultant in anaesthetics, Sunderland); E. T. Young, M.B., M.R.C.P. (consultant in geriatrics, Wansbeck); R. D. Peduzzi, M.B., F.R.C.S. (consultant in general surgery, East Cumberland); I. A. Fraser, M.B., D.P.H., D.C.H., D.P.M. (consultant in mental subnormality, Prudhoe); G H. Bevan, M.B., F.R.C.S.Ed., D.O. (consultant in ophthalmology, Newcastle)

NORTH-EAST METROPOLITAN REGIONAL HOSPITAL BOARD.—M. J. Harfst, M.B., D.P.M. (consultant in mental subnormality to South Ockendon Group of Hospitals); A. Pringle, M.B., M.R.C.P. (consultant physician in general medicine to Enfield Group of Hospitals); C. S. Ratnatunga, L.M.S., M.R.C.P. (consultant venereologist to Tottenham Group of Hospitals).

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—A. B. Herring, B.M., M.R.C.P (consultant neurologist, West Cornwall/Plymouth areas); J. A. C. Strachan, M.B., F.F.A. R.C.S (consultant anaesthetist (neurosurgery), Plymouth clinical area); R. A. Caldwell, M.D., M.R.C.P., M.C.Path. (consultant pathologist, Devon and Exeter clinical area (Exeter)); N. Edwards, M.B., F.R.C.S. (consultant ear, nose, and throat surgeon, Bristol clinical area); D. G. Calvert, M.B., F.R.C.S. (consultant in general surgery, North Gloucestershire clinical area); E. S. Lower, M.R.C.S., D.P.M. (consultant psychiatrist, Bristol clinical area); B. Murphy, M.B., M.C.Path. (consultant pathologist, Devon and Exeter clinical area (Torquay)).

Universities and Colleges

CAMBRIDGE

M.B.—Angela M. Birch (by proxy).

ST. ANDREWS

QUEEN'S COLLEGE, DUNDEE

At a Graduation Ceremonial on 4 July the following degrees were conferred:

M.D.—R. S. Bluglass.

PH.D.—*In the Faculty of Medicine*: D. Hopwood.

M.B., Ch.B.—[1]B. Gribbin, [2]Dorothy E. Roskell, [2]D. A. Newsome, [2]I. D. Duncan, [2]Diana F. Archer, [2]Margaret L. Elder, [2]Helen L. Dally, [2]J. H. Saywell, K. S. Aarnes, Elizabeth-Anne P. Adams, O. A. Afonja, K. J. Ball, J. R. Bell, D. H. Birrell, M. D. Blundell, D. T. Bunn, Catharine A. Ellis (or Chambers), D. Clish, T. D. Culshaw, D. G. Dalrymple, J. A. Davey, C. W. B. De Voil, V. U. Dewar, Marion M. Faulds, B. J. Green, R. W. Green, J. M. W. Grieve, A. J. L. Hart, A. Holme, M. A. King, A. G. Laing, B. E. Lambert, S. A. Lebeter, Anne G. Henderson (or Levison), A. M. McGregor, Alison L. Maitland, A. Mills, Claire V. Moore, H. G. Morton, D. J. C. Neilson, A. J. Ogilvie, K. M. O'Neill, Doreen G. Pae, K. Persad, B. B. K. Pirani, Clare A. Pirie, W. T. N. Pitkeathly, P. H. Robinson, J. T. S. Sadler, Diana M. Shelton, Patricia M. Skilling, J. G. Slessor, I. S. M. Smart, D. M. Smith, J. G. Spencer, R. R. Sturrock, Christine Starkie (or Taig), D. R. Taig, I. W. Taylor, S. Thornber, W. C. Wakefield, Sylvia N. Pegg (or Wood), B. G. Woodruff.

DIPLOMA IN INDUSTRIAL HEALTH.—J. H. Abhechand, S. K. Dallal, N. Frank, G. McHugh, R. B. MacLaren, W. M. Prentice, H. J. Royall, J. C. Talbot.

DIPLOMA IN PUBLIC HEALTH.—H. M. Abbas, A. M. Davidson, K. S. Dawoud, E. M. Elamin, W. Geddes, A. A. Ibrahim, A. A. Idris, J. E. Kahirimbanyi, P. Psaila-Savona, G. Reid.

CERTIFICATE IN INDUSTRIAL HEALTH.—E. Bougas, J. Nathan.

[1]With honours. [2]With commendation.

GLASGOW

M.B., CH.B.—*In absentia* by diploma: N. I. McPhail, Christine E. Robertson.

ABERDEEN

At Graduation Ceremonies on 6 and 7 July the following degrees were conferred:

HON. LL.D.—A Neuberger, M.D., Ph.D., F.R.S., professor of chemical pathology in St. Mary's Hospital, University of London, since 1955.

HON. D.D.—A. Craig, M.B., D.T.M., Church of Scotland Medical Missionary, Charteris Hospital, Kalimpong, since 1937

M.D.—[1]N. B. Bennett, [2]M. L. Diament, [2]W. McA. Easson (*in absentia*), R. A. Bennet, R. B. Gove (*in absentia*), Audrey Sutherland.

PH.D.—*In the Faculty of Medicine*: H. N. A. F. Fattah, J. H. Steyn.

M.B., Ch.B.—[1]Kathleen I. M. Watt (*née* Buchan), [1]Elizabeth S. Whiteford, [1]A. D. H. Wyllie, [2]Helen M. Adam, G. G. Aitken, R. M. L. Anderson, A. J. O. Antao, E. H. H. Austin, G. Barclay, J. A. G. Beattie, I. S. D. Begg, Mary R. Bell, Helen M. A. Birkbeck, H. T. Bruce, A. F. Chung, D. A. Cook, Diane P. Cramb (*née* Lawrie), A. E. Donaldson, C. G. Duncan, Elizabeth J. W. Duthie, H. McM. Dyer, I. H. Farquhar, H. G. M. Forsyth, B. Gill, J. F. Gordon, R. B. Gordon, R. W. Grant, W. F. D. Hamilton, F. B. A. Harhara, D. R. Harper, E. C. Jamieson, F. D. Johnstone, I. C. Keith, Frances Kelly, B. McCombie, Shina A. MacDonald, G. H. McIntosh, Doris M. McLean, A. Macmillan, J. W. McNab, I. D. McPherson, Elizabeth-Anne Marsh, J. Masing, D. G. Millar, A. H. Milne, G. T. Morrice, A. Munro, R. Murray, D. Pariente, Heather M. Petrie, M. A. Pratt, C. T. Preshaw, M. K. T. Puni, D. Reid, K. B. Ritchie, G. L. Robertson, D. G. Ross, Jill M. Savege, Lise Schirmer, M. McG. Scott, A. T. Shennan, Margaret E. Stephen, Helen M. R. Stirrat, I. W. Strang, I. A. Sutherland, J. R. Tallach, P. B. Taylor, Kathleen A. Tocher, J. F. Walker, I. C. F. Wisely, Susan E. Wood.

The following prizes and medals were awarded during the session 1966–7: *Anderson Medal and Prize in Clinical Medicine*, Kathleen I. M. Watt, (*Proxime accessit*) A. D. H. Wyllie. *Cash Medal for M.D. Thesis*, Audrey A. Dawson. *Chanock Medal in Anatomy*, and *Durno Prize in Anatomy*, G. P. M. Crawford. *Dyce Davidson Medal in Materia Medica*, and *Ogston Prize in Surgery*, G. R. D. Catto. *Matthews Duncan Medal in Obstetrics*, and *MacQuibban Prize in Surgery*, A. D. H. Wyllie. *Fulton Essay Prize in Neurology (1966)*, J. W. McNab. *Harry D. Griffith Prize in Medical Physics*, Leong Y. K. Leung Sui Fung. *Keith Medal in Surgery*, D. R. Harper. *Lizars Medal in Anatomy*, J. R. C. Logie. *McQuibban Prize in Medicine*, Kathleen I. M. Watt. *Faculty of Ophthalmologists' Prize*, Susan E. Ridley. *Shepherd Memorial Medal in Surgery*, Elizabeth S. Whiteford. *Davidson Smith Prize in Child Health*, Elizabeth J. W. Duthie, (*Proxime accessit*) A. D. H. Wyllie.

Appointments.—Dr. R. E. Mackie (senior lectureship, Department of Mental Health), Dr. M. G. Lyall, Dr A. B. Matheson (terminable lecturers, Department of Anatomy); Dr A Q Gardiner (terminable lecturer, Department of Mental Health).

[1]With honours. [2]With commendation.

EDINBURGH

At a Graduation Ceremonial on 19 July the following degrees were conferred:

M.D.—D. H. Clark, W. F. Coulson, [1]D. Doyle, J. S. Fleming, J. D. E. Knox, H. J. S. Matthew, [2]E. B. Ritson, [2]B. J. Wilken.

CH.M.—[2]J. A. Campbell, [1]B. H. Colman.

D.LITT.—D. J. Guthrie.

PH.D.—*In the Faculty of Medicine*: J. D. Cash, [2]D. C. Flenley, H. C. Guldberg, M. G. Mustafa.

M.B., Ch.B.—A. D. Adams, I. A. Archer, A. A. M. Aluaqi, A. S. Banks, A. R. Barlow, E. W. Barnes, R. D. Barnes, H. W. Bauld, E. I. Beckett, R. A. F. Bell, Hilda F. Bennett, D. B. Bennie, J. J. K. Best, A. B. Blyth, Susanne Boyce, W. B. Broadbent, J. V. Brooke, M. J. K. M. Brown, D. G. D. Campbell, Judith A. Campbell, Rosemary A. Cathels, W. B. Clark, Shirley Clarke, Affra M. V. Cocks, N. J. Cooke, A. Craig, Mary M. K. Craig, G. A. Crouch, D. C. Cumberland, J. A. G. da Costa, M. P. Daly, Pamela Davidson, J. M. M. Dey, R. A. Dickson, R. G. Donald, D. S. Dummer, R. A. Fawcitt, Jane E. Fleischmann, G. I. C. Fletcher, Margaret R. Flux, I. S. Fraser, J. French, H. M. Gilmour, K. A. Grant, [2]D. I. Grieve, Claire E. M. Guthrie, A. H. Habel, T. K. Hanid, A. D. B. Harrower, P. V. Harry, C. S. Haw, D. B. G. Hawker, P. C. Heaney, R. N. Hodges, R. Hodkinson, E. P. Hughes, Gwendoline Hughes, N. G. Y. Huseini, M. L. J. Jesudason, M. H. Kaufman, A. J. King, Jennifer A. King, Alison Leach, O. Ll. Lloyd, J. B. Loudon, Anne C. Lowe, R. A. A. Macaulay, J. M. F. McClemont, D. M. MacDonald, T. D. McGhee, Elizabeth H. M. McIntosh, G. B. McIntyre, M. J. McKitterick, E. H. McLaren, A. Macleod, R. S. Miles, Evelyn McK. Millar, A. W. Morrison, S. D. Moss, Frances M. C. Neilson, R. J. Nixon, O. A. Oyemade, A. C. Parker, W. D. Paterson, Cynthia G. Patient, Elaine Pemberton, C. W. G. Peterkin, G. N. Phillips, Sheila Picken, D. Poole, B. Rapoport, J. Rees, K. C. Riddell, A. W. Rifkind, Elizabeth M. S. Robertson, R. Robertson, Sheena S. Robertson, J. Robinson, M. E. Rodgers, Teng-Siam (née Cheah) Rodgers, P. Roscoe, M. J. Rowe, J. A. Russell, P. R. Samuel, P. J. Scott, F. R. Sharp, A. C. A. Smith, J. H. Spenceley, C. Thomson, I. M. G. Torkington, R. D. Turner, N. J. Vetter, T. A. Wadrop, S. A. Walker, J. M. Wallace, I. E. West, R. J. West, J. Whyte, S. R. Wild, D. N. Williams, J. B. Woolridge, W. S. Young.

Diploma in Medical Radiodiagnosis.—Valerie A. Briggs.

Diploma in Social Medicine.—Muriel I. K. Berkeley, J. D. Egdell, A. C. Irwin, W. B. C. Robertson, Elizabeth M. Russell, J. M. Tainsh.

Diploma in Tropical Medicine and Hygiene.—M. Hafezuddin, H. Kabir, M. O. Abdullah, A. A. Ali, A. S. M. M. Haque, M. M. Khakoo, A. W. Khalil, C. P. Kilala, E. N. Mngola, A. S. Nakadar, G. A. Noori, M. R. Qureshi, A. Rahman, T. B. Thapa, A Z. A. Zaidi.

The following Fellowships, etc., were awarded in the Faculty of Medicine: *Ettles Scholarship and Leslie Gold Medal in Medicine*, J. A. G. da Costa and Alison Leach (jointly). *Scottish Association for Medical Education of Women Prize, Mouat Scholarship in the Practice of Physic, Beaney Prize in Anatomy and Surgery, Dorothy Gilfillan Memorial Prize, Keith Memorial Prize in Systematic Surgery, 1936 Year Class Prize in Surgery, Annandale Gold Medal in Clinical Surgery*, Alison Leach. *Buchanan Scholarship in Obstetrics and Gynaecology*, I. S. Fraser. *James Scott Scholarship in Obstetrics and Gynaecology*, P. Roscoe. *Conan Doyle Prize*, B. Rapoport. *Lawson Gifford Prize in Obstetrics and Gynaecology*, R. Robertson. *Murdoch Brown Medal in Clinical Medicine*, D. N. Williams. *Graduate Research Fellowships*, Elizabeth Edmond, C. F. A. Whelan. *Graduate Research Scholarships*, R. N. Baird, R. A. Clark, B. Hawley, Jean C. MacPhail, Marie M. Ogilvie, I. R. Williams. *Graduate Travelling Scholarship*, F. W. Winton. *Lawrence Poole Prize in Rehabilitation after Poliomyelitis*, K. Vainio. *William Leslie Prize in Medicine*, I. M. L. Donaldson. *Chest and Heart Association Scottish Branch Undergraduate Prize*, B. Covell and M. J. Rowe (jointly).

Appointment.—Dr. E. R. Jay (lecturer, Department of Diagnostic Radiology).

[1]Commended for thesis. [2]*In absentia.*

DUBLIN

Trinity College, School of Physic

M.D.—R. Sinniah.

M.B., B.Ch., B.A.O.—B. W. Abbott, C. W. G. Angus, Edith S. M. J. I. Bacik, M. Blackman, J. R. Bradshaw, Jill Burland, R. L. Crowdes, T. E. B. Dane, C. N. O'N. Digges, R. J. R. Elmes, R. J. Fitzgerald, D. S. Freedman, G. F. Gervais, Kathleen A. Huey, Hung Soo Loh, Brigid J. McGinn, Frances P. M. Malone, J. S. Martin, P. E. Michael, F. R. I. Middleton, Jacqueline H. J. Milliken, Gillian J. Montgomery, C. C. M. Morrison, M. Mowbray, J. R. Nixon, T. H. Peirce, D. A. H. Rolfe, K. Sarda, R. G. K. Watson.

Diploma in Psychological Medicine.—*Part I:* Gladys M. Caskey, Jane A. Devitt, Mary Green, P. M. Kelly, Ruth Mitchell, D. M. Peppard, Mary E. T. Sheridan, M. J. Sweeney, M. M. Vanya, Joyce H. Weir. *Part II:* S. A. Ahmed, A. D. Duffy, A. Gravina, S. B. Sachs.

Diploma in Gynaecology and Obstetrics.—B. A. M. Al-Chalabi, B. Al-Niami, M. Khonji, S. Nizami, Q. Pabaney, S. T. Suhaly.

NEWCASTLE UPON TYNE

In Congregation on 1 July the following degrees were conferred:

M.D.—J. L. Gibbons.

Ph.D.—*In the Faculty of Medicine:* N. Bolton, P. G. Britton, M. Worsfold.

M.B., B.S.—A. O. G. Adeuja, S. K. Adjei, G. J. Aitken, Penelope E. M. Allan, S. F. Baker, Rosemary J. Berry, Alison M. Binks, F. D. Burke, R. H. Burr, Elizabeth A. Byers, Anne P. Charlton, R. J. Collingborn, D. B. Coltman, Wendy R. Cooper, Lesley Craft, Margaret C. Davison, A. M. Deall, D. S. Dry, W. A. Duke, S.-E. Ekeid, Elizabeth M. Foreman, R. Garry, R. F. Gillie, Anne H. Hagyard, D. G. Harle, P. Harrigan, Mary U. Hickey, P. S. Hogg, M. F. Humphreys, J. Hunton, Alexandra M. Hutson, H. U. Ihezue, S. T. R. Isherwood, Moira Johnston, T. Kelly, R. Y. Kendal, Susan H. Kinghorn, Elizabeth A. Lidster, D. T. Lord, Elizabeth G. Maddison, D. C. Marr, B. Marshall, W. M. Melrose, T. L. Moody, M. J. Mowbray, Dorothy M. Muir, J. M. Myers, Jennifer M. Naisbitt, Margaret Ormston, R. A. Pearson, Rosalind M. F. Sanderson, B. D. Shah, D. R. S. Smith, I. Stafford, P. J. B. Tilley, A. K. Vaid, Margaret Walton, C. L. Wheeler, M. Wilkinson, P. Willis, H. G. Wills, P. D. Wright.

LONDON

Dr. P. Curzen has been appointed to the readership in obstetrics and gynaecology tenable at Charing Cross Hospital Medical School.

Dr. Katharine G. Lloyd-Williams has been appointed a representative of the university on the council of the Royal Free Hospital School of Medicine.

The following have been recognized as teachers of the university in the subjects indicated in parentheses: *Institute of Child Health*, Dr. M. C. Berenbaum, Dr. J. F. Soothill (immunology), Dr. June K. Lloyd (paediatrics). *London Hospital Medical College*, Mr. J. P. Blandy (surgery), Dr. J. S. Pegum (dermatology). *St. Mary's Hospital Medical School*, Dr. C. A. Cheatle (anaesthetics), Mr. A. J. Harrold (orthopaedics), Dr. Doreen Rothman (obstetrics and gynaecology), Dr. P. H. Fentem (physiology), Dr. A. P. Fletcher (biochemistry). *Institute of Psychiatry*, Dr. W. G. Dewhurst, Dr. M. G. Gelder, Dr. M. Ll. Rutter (psychiatry), Dr. C. Rashbass (physiology). *Middlesex Hospital Medical School*, Dr. G. Farrer-Brown (pathology), Dr. C. B. Hobbs (chemical pathology). *Royal Postgraduate Medical School*, Dr. J. R. Hobbs (chemical pathology), Dr. R. H. Thomlinson (experimental pathology). *Institute of Orthopaedics*, Mr. H. B. Stafford Kemp (orthopaedics). *Royal Free Hospital School of Medicine*, Dr. M. R. Wills (chemical pathology). *St. Thomas's Hospital Medical School*, Dr. D. A. H. Yates (physical medicine). *Institute of Obstetrics and Gynaecology*, Dr. J. H. Smitham (radiology). *St. Bartholomew's Hospital Medical College*, Dr. G. H. Fairley (medicine).

M.D.—J. F. Arthur, D. J. Galton, H. Hunter.

M.S.—A. W. F. Lettin.

Ph.D.—*In the Faculty of Medicine:* Rosalind H. M. Ballin, D. F. Biggs, R. N. Boyes, H. G. Dixon, P. J. Holloway, J. F. Howes, G. A. Khan, A. Nasrallah, M. S. Starr, J. Thomas, R. O. Weller, J. E. Rees, A. R. Salim.

The following candidates at the London School of Hygiene and Tropical Medicine have been approved at the examinations indicated:

Ph.D.—*In the Faculty of Medicine:* M. F. Coldman, D. J. Ringshaw, H. O. Obianwu.

Academic Postgraduate Diploma in Public Health.—A. B. Allen, R. M. Badminton, *M. L. Burr, P. S. C. Cheh-Seeyave, P. N. Christie, P. J. Christopher, P. H. Cima, I. J. Cope, I. P. Crawford, S. Dharmavaratha, J. V. Earle, D. M. Fanning, A. M. M. Faris, A. Frame, W. L. R. Gibb, N. Govan, Ann B. Gray, D. W. K. Heendeniya, W. R. Henwood, Rosemary A. Hill, Vera M. C. B. P. Hollyhock, J. P. Hutchby, E. G. A. Jackson, E. Kangesu, H. G. Knox, K. Kooros, J. G. McL. Mortimer, S. A. Orzeszyna, Elizabeth J. Pritchard, *M. G. H. Rogers, A. V. Sheard, M. V. Smith, R. Sundaresan, Christine M. Thompson, Betty P. Westworth, M. C. T. Wilkes, D. S. Wright, C. Yoshida.

Academic Postgraduate Diploma in Tropical Public Health.—N. A. Atoot, M. M. Ayub, M. M. O. Beiram, B. C. Dando, Y. P. Cope, A. J. N. M. De Campos, Q. y A. Ferrer, A. Jamshidi, F. M. Khalifa, A. O. Marquez, A. D. Niazi, Q. M. Qhobela, Fidelina Regis, *Hilary M. Rowson, F. M. Shattock, S. Wongthai, *Yap Siew Khim.

Academic Postgraduate Diploma in Applied Parasitology and Entomology.—G. H. Dukes, H. N. Espinola, M. S. S. Gassouma, B. W. M. Gooneratne, S. L. Gorbach, Salome H. Gyaw, Z. G. Hayatee, L. Ilmolelian, J. M. R. Jjumba, Mary E. J. Mansfield, S. J. Mchinja, *Patricia M. Preston, N. T. Talbot, U. Winn, R. A. Ward.

Academic Postgraduate Diploma in Clinical Medicine of the Tropics.—S. A. Barnett, Y. D. Coble, P. T. Fox, S. E. Sama, M. G. Schultz, S. Shaikh, H. Sherief, E. B. Smith, P. Suntharasamai, M. S. Wolfe.

*Awarded a mark of distinction.

BIRMINGHAM

At a Degree Congregation held on 7 July the degree of D.Sc. *honoris causa* was conferred on Sir Derrick Dunlop, M.D., F.R.C.P.

The title of honorary research fellow has been conferred on Dr. B. H. B. Robinson (Department of Experimental Pathology) and Dr. C. I. Scott (Institute of Child Health) for the period of their work in the University.

Appointments.—Dr. J. A. Bushman (research fellow, Department of Anaesthetics); Dr. J. Herbert (lecturer, Department of Anatomy); Dr. A. Munro (senior lecturer and first assistant, Department of Psychiatry).

LIVERPOOL

M.D.—M. J. Brindle, G. J. Fairhurst, W. F. W. E. Logan, J. A. Wilson, P. J. J. Wren.

Ph.D.—*In the Faculty of Medicine:* A. B. E. Abdalla, D. J. Etherington, R. M. Green, R. Kellner, Elizabeth M. O'Ryan.

Ch.M.—P. T. Bruce, G. E. Dimopoulos, G. Sreēnevasan.

M.Ch.Otol.—W. Y. Nasser.

M.B., Ch.B.—[1,3,4]D. Owens, [1,4,5]Christine I. Riley, [2,5]Lydia A. Ellidge, [2,5]Jennifer Hughes-Nurse, [2,5]Valerie M. Inchley, [2,4]Rosalie P. Newsome, D. J. Allan, J. R. Allen, R. S. Arnold, K. G. Barrand, R. V. Brittain, R. M. Broadley, P. T. Bull, C. Bunting, N. R. Burford, P. L. Burke, R. Burrows, P. Buscombe, T. J. Butler, Jennifer M. Caile, Lesley J. Carter, J. J. Chambers, Cicely R. Chandler, J. S. Christie, J. E. Cleary, Christine M. Coates, A. I. M. Cook, D. J. Cooper, R. F. Dale, Patricia A. L. Denson, C. H. Dickie, P. J. Dixon, D. C. Egerton, A. G. England, Jane Flanagan, Wendy A. Freaker, V. N. L. Gohil, Margaret E. Green, M. G. E. Greensmith, Sandra L. Gregson, S. K. Hardy, D. S. Heath, Rosemary Henley, W. S. Henry, Adele M. Horley, J. R. Hughes, Doris K. Jagodzinska, J. T. Jenkins, D. Jenkinson, J. G. Jones, M. B. Jones, P. J. Lane, C. A. Lund, E. G. Lyon, Barbara M. McDougall, Catharine McGuire, G. S. Macmillan, Hilary J. Marcham, M. E. Mass, C. J. Molodynski, I. J. F. Morle, Valerie M. J. Muir, Edina M. Nakielna, C. W. Nicholls, Ruth D. Partridge, P. B. O. Pencharz, I. D. Plant, Celia M. Prinn, R. I. Pritchard, M. P. Quinlan, Winifred J. Robson, M. J. Rose, P. K. M. Rostron, K. Rowland, Carol J. Sage, A. W. Smerdon, S. L. Snowdon, C. W. Spencer, D. S. I. Taylor, A. Thomas, I. D. Tyson, [5]M. K. A. Varia, D. Vasey, D. M. Vickers, T. R. Watson, P. Webb, M. Weiner, P. A. Westwood, Elizabeth V. Williams, K. F. Woo, D. N. Yardley. *Passed in separate subjects:* A. G. Brown and A. J. May (medicine and obstetrics); J. J. Cockburn, M. Dalziel, J. R. Garcia-Valarino, and P. J. Gore (surgery and obstetrics); C. J. Hope (medicine and surgery).

Appointments.—Dr. D. V. Roberts (senior lecturer, Department of Physiology); Dr. K. Lubkiewicz (lecturer in child health); Dr. K. N. Brown, Dr. A. A. Deutsch, Dr. I. H. Emery, Dr. T. P. E. Nener (demonstrators in anatomy).

[1]With first-class honours. [2]With second-class honours. [3]Passed with distinction in medicine. [4]Passed with distinction in surgery. [5]Passed with distinction in obstetrics and gynaecology.

LEEDS

M.B., Ch.B.—[1]N. C. Barraclough, [1,2,3]J. C. Cawley, [1]D. F. Chapman, [1]R. Dakin, [1]Jean M. Graveney, [1]Rosemary A. Hoar, [1,3]Carolyn E. M. Jones, [1]V. K. Modgill, [1,2]G. J. S. Parkin, [1]M. R. Warren, [1,2]R. Wray, Susan J. Allan, D. W. Allen, F. Allenby, M. R. Banks, R. M. Barr, Jane L. Baxter, J. Bentley, Diana E. Brice, Jane E. Burrell, Gladys M. Cammish, Hazel P. Compton, J. S. Donohue, Sheila M. Donohue, S. W. Farrar, J. D.

Fenwick, J. A. Finnegan, M. C. Galvin, G. C. Goodman, G. P. Hall, J. L. Hancock, K. Hutchinson, Cathleen M. Jennings, Lucia A. Jones, Angela L. King, K. Liddell, R. W. Lodge, K. C. MacIntosh, A. R. MacKay, N. R. Matthews, M. H. Mehta, Mary S. Morris, P. M. Norton, J. V. Parkin, H. I. Rein, M. E. T. Roberts, G. B. Sacks, P. A. Shand, S. H. Shaw, Jennifer E. Storer, S. G. Tan, R. C. True, D. F. Wigglesworth, B. D. Willis.

D.P.M.—J. L. Barton, Beryl M. Bromham, A. K. Choudhuri, W. Galley, M. A. Hill, C. R. Samanta, Jenifer A. Shaw.

[1] With honours. [2] With distinction in medicine. [3] With distinction in obstetrics and gynaecology.

SHEFFIELD

Titles conferred.—Dr. J. K. A. Beverley (reader in medical microbiology); Dr. V. Dubowitz (reader in child health).

Appointments.—Mr. D. C. A. Bevis (full-time senior lecturer in obstetrics and gynaecology); Dr. I. B. Pearson (full-time lecturer in psychiatry); Dr. J. R. Cox (part-time clinical teacher in medicine); Mr. I. Hopper (part-time honorary clinical tutor (ear, nose, and throat)); Dr. P. G. Small (part-time honorary clinical tutor (radiology); Dr. R. S. Smith (part-time honorary lecturer (haematology) within the Department of Pathology); Mr. D. F. L. Watkin (part-time honorary clinical tutor (surgery)).

QUEEN'S UNIVERSITY OF BELFAST

M.D.—[3]S. S. A. Fenton, W. B. Loan, R. A. McNeill, R. H. McNeilly, W. W. Ramsay, T. J. Robinson, J. O. Woods.

PH.D.—*In the Faculty of Medicine:* D. W. Barron, J. S. Chopra, P. Froggatt, A. G. Garg, A. H. M. Lutfi, S. P. Parbhoo, [3]M. N. Rashad.

M.B., B.CH., B.A.O.—[1]P. Kennedy, [2]Helen Mawhinney, [2]J. S. Robinson, I. O. Achike, N. A. Akingbehin, L. L. Bailie, P. J. S. Baker, J. D. Boyd, D. A. Boyle, S. Brown, Elizabeth M. Bryars, P. O. Burton, J. G. Camblin, Ruth E. Carson, Frances Chambers, W. J. Charles, M. J. Cinnamond, P. F. Crowe, Judith A. Dennis, R. E. Dibble, Mary E. C. Donnelly, R. K. Eccles, F. R. Elder, Margaret E. L. Elliott, Mary E. B. Elliott, F. B. T. Forbes, J. H. Gaston, D. H. M. Groves, B. D. Hanna, J. R. W. Harris, T. W. Hayes, Mary J. Hollinger, Eileen A. Irwin, R. G. G. James, H. A. Jefferson, H. C. Johnston, J. E. Johnston, P. G. M. Kelly, Barbara E. Kernohan, A. R. F. Kerr, Barbara Leitch, A. G. Leonard, W. D. McCallum, R. J. McClelland, Margaret E. McCrory, R. McK. Martin, R. Millar, T. D. Miller, Jennifer A. Milligan, Margaret R. Mitchell, R. C. Montgomery, B. J. F. Morgan, [3]T. C. M. Morris, C. K. Munro, Rosemary J. Orr, J. R. Palmer, F. Patterson, Josephine M. Patterson, B. Peoples, M. R. Phillips, G. F. W. Price, H. C. Ramsey, J. W. Richardson, Joan A. Russell, [3]S. M. Then, Elizabeth R. Trimble, S. Z. H. Wafa.

[1] First-class honours. [2] Second-class honours. [3] *In absentia.*

BRISTOL

M.B., CH.B.—[1] [2]Elizabeth J. Leese, [1]Barbara R. A Maddox, [1]I. M. Vickery, C. Adey, G. A. J. Appleby, A. F. Avery, A. A. J. Barros D'Sa, R. E. Barry, A. F. Boyles, B. J. Burke, Prunella E. Caville, S. K. M Chan, Margaret C. Clark, P. B. Clark, A. G. Clarke, D. F. Cochrane, Yahia F. Dajani, Maureen I. Delves, D. W. Felce, Susan Gage, D. W. R. Gibson, T. J. Hamblin, W. A. V. Henderson, Vivien M. Hesketh, J. D. L. Holroyd, Margaret S. Jones, Sandra E. Mooney, W. J. Moore, J. F. Morris, H G. Oon, D. Poole, M. B. Roberts, M. J. Y. Ruck, [2]G. B. Salmon, Rosemary J. Simpson, D. J. T. Webster. *In Section I only:* R. M. Gannaway. *In Section II only:* A. J. Brown, B. J. W. Pingree.

M.D.—Bimla Arora, June M. Brown, P. F. Harris, E M. Sedgwick, I. Surveyor.

CH.M.—R. A. Sellwood.

PH.D.—*In the Faculty of Medicine:* L. M. Silverstone.

Appointments.—Dr. J. D. M. Blayney, Dr. A. E. B. Giddings (demonstrators in anatomy); Dr. J. Gough (lecturer in pathology); Dr. P. S. Hasleton, Dr. D. Robertson, Dr. M. R. Thompson (demonstrators in pathology); Dr. D. J. Moffatt (lecturer in anatomy).

[1] With second-class honours. [2] With distinction in public health.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

On 6 July Mr. H. Osmond-Clarke (London Hospital) and Mr. Robert V. Cooke (Bristol Royal Hospital) were re-elected and Mr. George Qvist (Royal Free Hospital) was elected Members of the Council of the College.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a recent meeting of the College the following candidates having passed the requisite examinations were admitted ordinary Fellows:

S. M. Aga, A. U. Ahmed, S. H. Aiyar, S. T. Al-Mufti, Md. N. Amin, M. Anwar, C. K. Asavanich, Min Aung, P. S. Bajaj, M. R. Baylis, R. Buntwal, A. F. G. Campbell, C. L. Chakrabarty, T. D. Chatterjee, K. A. Ul H. Cheema, F. Chi-Yan Cheng, J. F. Clegg, B. K. Devgan, W. A. Downie, M. S. H. El-Sawah, T. A. H. English, B. O. Fasehun, C. B. D'A. Fearn, F. Fleming, J. B. McG. Fleming, M. V. L. Foss, P. V. Godbole, J. H. Goldin, J. M. T. Griffiths, D. H. Gudgeon, S. S. Guindi, Om-Prakash Gupta, J. G. Guy, A. Hai Khan, K. A. Haq, K. P. Hardas, S. M. Hasan, A. I. Hasham, N. Hazari, A. D. Heath, K. M. Helmi, L. Henkel, D. A. W. Hopkinson, I. Hopper, M. J. S. Hubbard, A. K. C. Hui, J. O. Ikpeme, R. R. Ingle, S. Iskander, M. R. Islam, E. A. Jangda, P. J. E. Johnson, R. H. Johnson, V. K. Kak, V. K. Kapur, A. B. Kargbo, S. J. Karran, S. P. Kaushik, A. S. M. Abdul Khaleque, A. M. Khan, A. A. Kiely, A. K. S. Koh, A. D. W. Maclean, V. I. McCusker, J. J. Maeda, G. Mah, F. Mahmood, (Mrs.) Sabiha Mahmood, B. J. Masakorala, I. A. Miller, A. G. Mina, B. N. Misra, D. K. Mukherjee, D. K. Murray, M. R. Nicoll, J. N. Norman, K. D. Okey, D. F. Omalley, J. R. Pandey, (Miss) Naima S. Panow, J. D. Patel, R. Plotkin, B. J. Preston, (Miss) Zarina S. Qureshi, K. K. Ramalingam, M. H. Randhawa, M. J. Rao, M. K. Sahasrabuddhe, S. L. Sandhir, R. N. Sapsford, T. G. G. Scott, R. A. Sells, N. Selvarajah, R. P. Sengupta, P. H. Shah, G. Sham Sunder, J. D. Shaw, D. C. Shove, S. K. Sil, D. J. Simon, M. L. Singh, P. Singh, G. J. A. Siriwardena, C. L. K. Ssali, P. Y. F. Taikie, T. A. Talaat, R. K. Thakore, R. Thammari, J. Thomas, S. Venugopalan, T. R. Verma, A. Wahab, J. R. Wambwa, J. G. Wheeler, A. R. B. El Zawawi, A. F. M. Zuaiter.

At a recent meeting of the College the Honorary Fellowship was conferred upon Sir David Cuthbertson.

ROYAL COLLEGE OF PHYSICIANS AND SURGEONS OF GLASGOW

At a meeting of the College held on 3 July J. R. Ayers was admitted *in absentia* Fellow *qua* Surgeon.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At a meeting of the College held on 2 June the following were admitted to the Fellowship:

R. H. Bland, W. H. Hood, W. M. O. Purcell, J. C. McGoldrick, L. G. McElearney, M. D. Joyce, A. J MacDonald.

The following were admitted to the Membership:

F. R. B. Brown, A. T. Carty, E. B. Casey, Hean-Tat Goon, D. M. McCarthy, G. H. Tomkin, R. P. Towers.

At a meeting of the College held on 30 June the President, Professor Alan Thompson, admitted the following to the Licence in Medicine and Obstetrics:

W. T. Bishop, J. M. Blankson, S. Bokhary, S. A. Boodoosingh, R. A. Bourke, A. A. Bulbulia, M. A. H. Coovadia, S. Covenden, K. Dansoh, L. S. Dassama, R. Doraisamy, H. G. Falkenberg, I. R. Ghelani, R. A. Gorczak, M. S. Haffajee, R. F. Harrison, P. R. Hosein, C. F. E. Hudson, G. D. Hurley, P. J. Johnson, R. A. Joseph, Z. K. Kalapesi, R. Kānapathipillai, J. B. Kelly, M. Khan, M. A. Khan, M. Kirwan, J. A. Kirkby, M. M. Lee Chong Ken, M. H. Lokhat, G. R. R. Maharaj, J. D. G. Malone, K. P. Manning, I. S. Mebitaghan, J. A. Milne, M. Minty, E. M. Moola, A. K. Mula, S. L. B. Musani, M. B. McGill, H. C. O'Neill, O. O. K. Oye, F. M. Panchbhai, H. D. Patel, V. C. Patel, R. Ramdenee, R. N. Ramgoolam, R. K. Rattan, R. Ryan, J. O. Sehindemi, M. A. Shah, F Shannon, B. O. Soyemi, P. S. Tilluckdharry, Olu-Olusanya, L. Tunwashe, N. K. Whelan, Wong Peng Chee.

ROYAL COLLEGE OF SURGEONS IN IRELAND

On 5 July the Final Fellowship in Otolaryngology was conferred on the following candidates:

L. R. C. Bain, A. G. Evans.

On 7 July the Fellowship in Ophthalmology was conferred on the following:

F. L. Lavery, P. A. Tan.

COLLEGE OF PATHOLOGISTS

The following founder members have been promoted to Fellows:

M. K. Alexander, S. S. Alexander, B. E. Andrews, K. C. Basu Mallik, Isobel P. Boswick, R. P. Bradshaw, J. C. Burne, H. Caplan, H. R. Colquitt, I. M. P. Dawson, J. C. Edozien, A. H. Emslie-Smith, A. W. H. Foxell, R. K. Gadgil, N. R. Grist, W. A. Harland, W. G. Henderson, R. A. Holman, J. B. Howie, M. S. R. Hutt, K. G. Irving, H. C. Jeffrey, W. J. Jenkins, A. Kertesz, M. B. King, J. Kohn, C. J. P. La Touche, J. K. Lucas, R. H. McInroy, T. Manners, A. K. Mant, C. E. Marshall, K. M. Mattocks, M. S. Millard, D. L. Mollin, B. P. L. Moore, R. A. Neely, R. C. B. Pugh, S. S. Raphael, D. S. Ridley, G. B. S. Roberts, F. J. C. Roe, P. B. Schofield, G. B. D. Scott, J. G. Selwyn, J. A. Shrigley, D. R. Smith, P. B. Stones, A. D. Thomson, R. P. Towers, K. A. D. Turk, S. O. Waller, J. B. Walter, G. K. Welch, J. P. Whitehead, K. M. Win, L. Wolman, R. C. Woodcock, V. Wynn, A. Wynn-Williams, F. Fulton, Doris C. Peiris.

Deaths

Hutt.—On 8 July 1967, in St. Bartholomew's Hospital, London, Charles Wayte Hutt, M.B., B.Chir., of Minster, Isle of Sheppey, Kent, aged 56.

Kirkham.—On 16 July 1967, at his home, 59 Knowle Avenue, Ainsdale, Southport, Arthur Welsby Kirkham, M.B., Ch.B., aged 71.

MacDonald.—On 18 July 1967, in hospital, Donald Alexander MacDonald, M.B., Ch.B., of Chadwell Heath and Romford, Essex.

Corrections

Allopurinol.—We regret that the mention of allopurinol in the Today's Drugs article on "Hazards of Drug Prescribing in Pregnancy" (22 July, p. 220) was inaccurate.

Allopurinol acts by inhibiting xanthine oxidase and it is a valuable and relatively safe drug for use in gout and in some other conditions of hyperuricaemia. Thus allopurinol has been used as an adjunct in cancer chemotherapy to diminish hyperuricaemia and to improve the chemotherapeutic index of 6-mercaptopurine, which is oxidized by xanthine oxidase. The toxicity to the host of this combination is not necessarily increased to the same degree as is toxicity to the tumour. Allopurinol has not been shown to be teratogenic in man, neither is it mainly used in cancer treatment. The sentence in the article should therefore have read: "Apart from thalidomide, these are drugs mainly used in the treatment of cancer—antimetabolites (such as methotrexate and 6-mercaptopurine), alkylating agents (such as chlorambucil), and antibiotic substances (such as actinomycin D)."

Cyclandelate.—The manufacturers of Cyclospasmol have drawn attention to the article on cyclandelate in Today's Drugs, 3 June, p. 622. A starting dose of 100 mg. three times daily was recommended. Cyclospasmol is no longer manufactured in 100-mg. tablets, and the manufacturers recommend a starting dose of 200 mg. four times a day, which may be raised to 1,600 mg. daily if necessary. The recommended maintenance dose is 200 mg. b.d.

We regret that the name of the publisher, Butterworth & Co. Ltd., London, was omitted from the review of *Clinical Surgery: Abdomen and Rectum and Anus*, edited by Professor Charles Rob, Mr. Rodney Smith, and Sir Clifford Naunton Morgan (22 July, p. 224).

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON W.C.1. TELEPHONE: 01-387 4499. TELEGRAMS: *Aitiology, London W.C.1.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs.

ADVERTISEMENT AND SUBSCRIPTION ORDERS should be addressed to The Manager at B.M.A. House, London, or at 415 Bourke Street, Melbourne, Victoria, Australia.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the British Medical Association, B.M.A. House, London, or to the Scottish Secretary, B.M.A. Scottish Office, Drumsheugh Gardens, Edinburgh.

Chest Pain after Infarction

Chest pain is common among patients who have had a myocardial infarct. In the first few days after the infarct pericarditis is usually responsible, but arrhythmias may bring on ischaemic pain. More rarely pain in the first week heralds rupture of a papillary muscle or of the interventricular septum, though then severe dyspnoea and shock predominate. Pulmonary embolism becomes more frequent in the second week, and it may be confused with the post-myocardial infarction syndrome, which begins to occur at this time. Angina pectoris usually becomes evident as the patient starts to return to normal activity, though it may be felt earlier. These and other extra-cardiac causes need consideration before recurrent chest pain is attributed to extension of infarction, a diagnosis which is usually wrong.

Later in their convalescence patients may continue to feel pain of various kinds. Most experience at least transient discomfort,[1] and pains are often of more than one type. Angina pectoris is the most frequent of those which become established, though there are few systematic surveys of its incidence. In one series[2] about half the patients with no previous angina had developed the symptom when examined two to five years after their infarct. J. H. Palmer[3] found it in about 60% of patients after recovery from infarction (half of these had experienced it before their infarct). The most important feature in the diagnosis of this pain is its relationship to factors which precipitate or relieve it.

It has been estimated[4] that the post-myocardial infarction syndrome complicates 3–4% of cases of myocardial infarction. The complete syndrome is a triad of pericarditis, pleurisy, and pneumonitis, and it is most frequent two to six weeks after the infarct, though it may appear earlier or several months later. It is characterized by prolonged and recurrent chest pain and fever and by a strong tendency to relapse. Typically the pain is pleuropericardial, aggravated by breathing or change in posture. A pericardial friction rub is heard in 80% of patients with the syndrome, and pleural and pericardial effusions are common. The syndrome appears to be the result of an autoimmune response to injured myocardium and thus to resemble the post-cardiotomy syndrome. It is self-limiting and often requires no treatment apart from reassurance and relief of pain. Corticosteroids lead to dramatic improvement, but relapse often follows their withdrawal. Anticoagulants are dangerous and are contraindicated.

Professor R. R. H. Lovell and his colleagues in Melbourne have recently interested themselves in chest pain following myocardial infarction. During a follow-up period of between six months and three years 38% of their patients developed angina.[1] The next most common symptom was a pain in the left chest, which occurred, without angina, in 9% of the patients. Other authors[4 5] have commented on the occurrence of left chest pain after infarction and have found a similar incidence. This pain sometimes seems to upset patients more than does angina pectoris, which is more

predictable. It is usually described as being of a steady dull aching character and of mild to moderate intensity. It is not directly related to exertion but tends to occur towards the end of the day and often seems to come on when a patient has exerted himself rather more than he feels he ought to have done. It is frequently affected by movement of the body, and many patients have areas of localized tenderness over the chest.[6]

The mechanism of this left chest pain remains uncertain. It is unlikely to be ischaemic in origin, and has been likened to the pain of Da Costa's syndrome. It appears to be correlated with responsiveness of the sympathetic nervous system,[7] and Professor Lovell and Dr. A. Verghese show in their paper published this week in the *B.M.J.* at page 327 that it is also linked with neuroticism. They find in addition that patients with left chest pain tend to be long and narrow in body build and to be less fat than others. The authors indicate that these features have been shown to be linked with constitutional neuroticism and suggest that it might be worth trying to identify early in convalescence patients likely to develop these pains. Some of the disabling features of the pain might then be prevented. Once anxiety about it has been met with adequate reassurance and explanation the pain usually disappears or at least ceases to worry the patient.

Left chest pain has also been compared with the "frozen shoulder" and "shoulder-hand" syndromes, usually attributed to reflex muscular spasm and disturbances of sympathetic innervation. Disuse also is probably important, and these conditions are seen less frequently now that early mobilization after infarction is encouraged. They had previously been described as occurring in 10–20% of patients. Persistent pain may develop in one or both shoulders, usually with tenderness and limitation of movement.[8] Sometimes there is wasting of the shoulder muscles. In a minority of patients the hands are also affected, with stiffness, pain, swelling, and discoloration.[9] Dupuytren's contracture and other trophic changes are described. The pain can persist for many months, and may recur. Physiotherapy often helps, and infiltration with procaine or hydrocortisone may also do so.

Any pain in the chest or arm which occurs after the pain of myocardial infarction is commonly taken by the patient to indicate serious cardiac disease. The doctor too may misinterpret its significance or unintentionally transmit anxiety to the patient. Rehabilitation is then often held up without need, and A. J. Goble and his colleagues[10] have given a dramatic description of the incapacity which may ensue. It is the doctor's task to prevent this.

Risky Grandmothers in Rh Disease

Red blood cells from a foetus can pass through the placenta into the mother's blood stream, and most of this leak occurs during labour. It is this leak that sensitizes an Rh-negative mother who has an Rh-positive foetus, so that Rh-antibodies are produced by the mother's immunological system. When the mother becomes pregnant again she already has some Rh antibodies in the blood stream, and they can pass the placenta and affect the red cells of an Rh-positive foetus.

But often this sensitization does not occur. Figures vary from 1 in 19 to 1 in 23 of expected pregnancies, so that the incidence of children with erythroblastosis is much less than theoretically expected.[1] One of the attempts to explain the deficit has involved the role of the grandmother of the affected child—that is, the mother of the Rh-negative woman who has an Rh-positive child. It is sometimes not realized that maternal red blood cells can pass the placenta into the circulation of the foetus. R. R. Race and Ruth Sanger show from published reports that this can happen in 1 in 6 pregnancies or even more often.[1] Two theories about the effect of this maternal invasion have been proposed. One theory suggests that the passage of maternal cells may induce immunological tolerance in the foetus; the other theory is directly opposed and suggests that the passage of maternal cells increases the liability of the child to respond to Rh stimulation in later life.

Jane F. Taylor,[2] of Columbus, Ohio, has set out to investigate which of these theories is likely to be correct. She has done this by examining a series of families each consisting of a grandmother, her Rh-negative daughter, and the daughter's children. When ABO blood groups of mother and child are incompatible, foetal Rh-positive cells that cross the placenta may be destroyed before they are able to induce sensitization in the Rh-negative mother; consequently such families where this might occur were not included in the trial. She also eliminated any mothers who had been transfused, and did not include any non-white families. With these limitations, 157 out of the original 236 families were included in her trial and they were derived from two groups: families in which the mother had had a child affected by erythroblastosis in any pregnancy, and families referred for routine prenatal testing in which the mother had had at least three Rh-positive children none of whom had developed erythroblastosis. The grandmothers, the mothers, and the children all had their ABO and Rh groups determined, and erythroblastosis was diagnosed on clinical evidence and the occurrence of a positive direct antiglobulin test with the child's red cells and the presence of Rh antibodies in the mother's serum.

The results showed a statistically significant excess of Rh-positive grandmothers in the families who had an erythroblastotic child. In families with Rh-positive grandmothers 79% of the children had erythroblastosis, whereas in the families with Rh-negative grandmothers 60% of children were affected. By an ingenious calculation Taylor showed that the effect of the Rh-positive grandmother was equivalent

[1] Race, R. R., and Sanger, R., *Blood Groups in Man*, 1962, 4th ed., p. 387. Oxford.
[2] Taylor, J. F., *New Engl J. Med.*, 1967, **276,** 547.

to one Rh-positive pregnancy. Consequently Taylor firmly supports the view that the passage of maternal cells from an Rh-positive mother to her Rh-negative female foetus means that when the daughter bears children in her turn she will be more, not less, liable to have an affected child if her husband is Rh-positive. And the risk of erythroblastosis occurring in the daughter's children is about equivalent to one Rh-positive pregnancy.

Taylor also cites data which suggest that for the majority of Rh-negative women who have Rh-positive husbands the first child to be affected is most likely to be that of the third pregnancy. But the data from the examination of grandmothers suggest that if the woman has an Rh-positive grandmother the first affected child may well come from the second pregnancy. However, mothers in these circumstances should not receive too gloomy a prognosis from their medical advisers, because the rule still applies that only about 1 in 20 pregnancies that might result in a child affected by erythroblastosis actually does so.

Disorders of Defaecation in Children

Disorders of bowel habit in children are notoriously difficult to manage. To the mother failure in toilet training is considered to be a reflection upon herself, and she may make strenuous efforts to conceal the evidence of faulty control of the bowel in her child from relatives, friends, and doctors.

In considering the problem of abnormal bowel habits in children a clear distinction must be made between organic and "functional" disease. Apart from anatomical deformities such as anal stenosis, Hirschsprung's disease is the most important organic condition which must be considered. Symptoms of this disease are invariably present from the neonatal period, with prolonged periods without a bowel motion and accompanied by extreme gaseous distension of the abdomen or actual intestinal obstruction. The infrequent stools are small and "rabbity" in type, but occasionally an infant may present with severe diarrhoea. Thus any disorder of bowel habit with infrequent stools which comes on after a period of months or years of normal defaecation is almost certainly not due to Hirschsprung's disease.

In infancy, however, the passage of hard stools is not uncommon and may cause an anal fissure, with a resulting fear of defaecation. This may ultimately lead to voluntary retention of the faeces, which in turn become hard and painful to pass. A vicious circle may then be set up, which may last for many weeks or months. In the older child, on the other hand, faecal soiling is more difficult to evaluate. A detailed history will usually show whether the soiling is due to leakage of soft faecal material through the anal sphincter, or whether it is due to an involuntary or voluntary act of defaecation which is inappropriate in time and place. Constant faecal soiling is due to the softening of impacted faeces in the rectum and anal canal or to mucus and faeces leaking round a firm faecal mass. There is usually a history of a normal bowel habit until a period of constipation which is followed by faecal soiling: the cycle may be ended by the passage of a very large motion often described in revealing terms,[1] after which the sequence will be repeated. The circumstances which set off this dismal story can often be easily identified. A period of mild dehydration with constipation may accompany a febrile illness, a spell of hot weather, a long car journey, or a summer holiday—or an admission to hospital for a minor operation, or starting school, may be the initial cause. There is obvious perianal soiling, the anal sphincter is lax, and firm faeces fill the anal canal. There is no question of voluntary defaecation in such cases; the child may spend long periods attempting unsuccessfully to defaecate. Management is not easy in long-established cases; enemas and wash-outs should be avoided unless other measures fail, and most children will respond to the use of liquid paraffin initially followed by carefully regulated doses of proprietary senna preparations. A full explanation to both parent and child is essential. Nevertheless, relapse is common, and it is difficult to avoid the conclusion that in many instances there is an underlying emotional disorder in child or parents, or both, which prevents the re-establishment of a normal bowel habit.

Margit Bellman[2] in Stockholm has recently conducted a survey into "encopresis." Most of the children in this group had either never gained normal bowel control ("primary encopresis"), or had broken down after a period of normal control ("secondary encopresis"). Constipation did not play an important part in the troubles of these children, who seem to constitute a separate group from those with chronic constipation and faecal soiling. Dr. Bellman's findings are of interest. The condition was commoner in boys, and of the whole series encopresis was mentioned in the school record card in only 11%. The mothers of affected children tended to be over-anxious, and coercive pot-training was common. "Accidents" were punished severely, and yet at other times the mother was indulgent. The children were lacking in self-assertion and rarely had the normal period of defiance at the age of 2–3 years. Happily the majority had lost their bowel symptoms by the age of 10 years. Thus the conclusions of this interesting study seem to justify the introduction in 1925 of the distinctive term "enkopresis" by C. Pototsky.[3]

Musculo-skeletal Disorders after Renal Transplantation

A variety of skeletal and muscular disorders have been described after renal transplantation. They fall into three main categories: complication of high doses of corticosteroids, consequences of inadequate renal function, and changes in parathyroid function.

It is often necessary to treat patients with transplants with very high doses of corticosteroids, rising to as much as 200 mg. of prednisone a day during rejection crises. In addition to the usual features of Cushing's syndrome, demineralization of the bones may result in renal stones and pathological fractures. If the high corticosteroid dosage needs continuing it can stunt the growth of children. Arthropathy resembling gout can follow renal transplantation.[1] However, chemical analysis of the periarticular deposits shows high concentrations of calcium and phosphorus, with negligible amounts of urate. The joint surfaces themselves are not involved, and the lesions are probably due to a crystal-induced arthropathy which has been called pseudogout.[2] It has been reported in patients on chronic intermittent dialysis[3] and is probably due to insufficient dialysis, while in patients with renal transplants it is almost certainly due to poor function in the transplant.

Secondary parathyroid hyperplasia is a common sequel to long-standing renal disease. J. J. McPhaul and colleagues[4] described the development of autonomous hyperparathyroidism after restoration of renal function by a transplant. After transplantation there was marked hypophosphataemia, phosphaturia, hypercalciuria, and hypercalcaemia. Patients with this syndrome may require removal of the parathyroid glands to prevent formation of stones and decalcification of the bones.

J. F. Bravo and colleagues[5] have reviewed 60 long-term surviving patients with renal transplants, the mean follow-up being 491 days from operation. Of these patients 38% had one or more clinical signs of connective-tissue disorder, apart from muscle weakness, skin diseases, osteoporosis, or neuropathy. Five patients suffered from avascular necrosis of the bone, five from synovitis, thirteen from arthralgia, and ten from diffuse musculo-skeletal pain. Anti-gammaglobulin activity against human globulin was found between the second and twenty-eighth weeks after operation in 93% of cases regardless of the presence or absence of rheumatic disorders. Antibodies to deoxyribonucleic acid and ribonucleic acid were found in 40% and 28% respectively. These workers were unable to detect antibodies to specific constituents in synovial membranes, skeletal muscle, blood vessels, liver, or kidney. Determination of plasma lipids[5] showed fluctuating abnormalities in free and esterified cholesterol, phospholipid, triglycerides, non-esterified fatty acids, and total lipid levels. The synovial fluid consistently showed both intracellular and extracellular refractile, oval, lipid-staining particles varying from less than 1 to over 25 μ in diameter. Bravo and colleagues suggest that the aberrations of lipid metabolism may be secondary to corticosteroid therapy. The very high incidence of the rheumatoid factor in the serum in patients with transplants is of interest, though the mode of production of these antibodies is at present unknown. Humoral antibodies were not found in transplants between twins.

It would seem likely from the work of Bravo and colleagues that all patients with renal homografts from donors other than twins would eventually develop rheumatoid factor in the serum, but there was no apparent relationship of the appearance of the rheumatoid factor to the pathogenesis of the connective tissue disorders, since the activity appeared regardless of the presence or absence of rheumatic complaints. The severity of rheumatic disturbances was not related to variations in dosages of immunosuppressive drugs. However, J. P. Jones and colleagues[6] found evidence of fat emboli after rapid reduction of corticosteroid therapy, and fat embolism could be a cause of avascular necrosis of bone.

It is most important that evidence of muscular and skeletal disorders after kidney transplantation should be sought continuously, since early treatment may prevent disastrous consequences, particularly in hyperparathyroidism, when surgery can be entirely effective. There would seem to be a need for caution in suddenly changing corticosteroid doses, and no patient should be kept on high doses longer than is absolutely necessary. If good transplant function can be maintained, the pseudogout arthropathy will not develop.

Dangers of Squint

The harmful effects that a squint may have on visual function are not always realized, so that delay in diagnosis, and hence of treatment, is of more frequent occurrence than it should be. The condition is fairly common in children. In fact the clinical study carried out in Manchester and Salford by Drs. A. M. Adelstein and John Scully reported at page 334 of the *B.M.J.* this week showed that over 4% of 6-year-old children had it.

The most serious sequel of untreated squint is amblyopia of the affected eye due to suppression of part of the vision, and it may eventually go on to loss of useful sight in that eye. It is by this process that a child with a squint may overcome the diplopia and confusion which tends to occur when the eyes are constantly looking in different directions. On the other hand a child with a squint may attempt to co-ordinate the function of both eyes by using the fovea centralis of the fixing eye in conjunction with an eccentric point on the retina of the squinting eye. This may operate only when both eyes are open, the squinting eye rapidly resuming foveal fixation if the other eye is covered. It is known as "anomalous retinal correspondence." However, if this abnormal association between the two eyes becomes more stable, the squinting eye may still tend to view a fixation object eccentrically in spite of the other eye being occluded, though the fovea maintains its normal directional value. Such eccentricity of viewing may later give way to "eccentric fixation," in which the eccentric point of fixation becomes relatively stabilized and assumes the principal visual direction of that eye. Eccentricity of fixation is in most cases associated with considerable amblyopia in the squinting eye, and prolonged treatment is usually required to overcome it. It is only in a squint freely alternating from eye to eye or an intermittent squint that really good vision is retained in each eye.

Statistical evidence in Adelstein and Scully's paper shows that the percentage of children with non-central viewing increases as the interval between onset of squint and its diagnosis (and effective treatment) increases. Furthermore it is most frequent in those children who start squinting early in life and less frequent when the squint starts later. This emphasizes the need to refer a doubtful case of squint immediately to an ophthalmologist, so that early treatment can be undertaken. Though a squint of large degree is more likely to attract attention than one of small degree, the adverse affect on visual function may be just as serious in the latter. Every clinician should be familiar with the method of diagnosis of squint by means of the cover test.[1]

Adelstein and Scully have also shown that the longer the interval of time between onset of squint and diagnosis the greater the percentage of children showing non-central viewing. Non-central viewing was most frequent in those who developed a squint at an early age, and the frequency decreased progressively as the age of onset increased, but the trend of decrease was not shown in the group of cases showing the longest interval of time between onset and diagnosis. They also found that a difference in refractive power between the two eyes of two or more dioptres predisposed towards eccentric viewing, and that it was proportionately slightly more frequent in boys than in girls. Furthermore, there was also a tendency for the onset of squint to be commonest in the winter months, with a peak in January.

---

[1] Wybar, K., in *Child Care*, p. 223. 1966. British Medical Association, London.

Although in Manchester and Salford the percentage of cases of squint diagnosed within a year of its onset was about 80–90% in children who began to squint between the ages of 2 and 6, it was considerably lower among those who began to squint at an age of under 1 year, indeed only about 50%. This is no doubt due to the old-fashioned idea that very young infants are too young for diagnosis and treatment. No infant is too young for examination and diagnosis nor for treatment by occlusion (if indicated). In some cases, for instance those of freely alternating squint, the early management may, in the absence of relevant errors of refraction, merely consist in periodic and careful observation. Moreover, the clinician must always bear in mind that a squint may be the outward sign of some serious ocular disease or may be paretic in nature and due to some underlying neurological disorder necessitating further investigation.

It is not always realized that a constant unilateral convergent squint which might otherwise end in a relatively blind eye may, as a result of timely occlusion, become converted into one of freely alternating convergent squint. This will ensure that both eyes keep good vision, and subsequently if the squint is controlled by correction of the refractive error or by surgery and orthoptic treatment or both the child may attain binocular single vision or, failing that, some useful form of binocular association. The development and preservation of good vision in each eye of a young child is a duty which every ophthalmologist must accept, but in order to discharge this duty he must rely on the early referral of all cases of squint by general practitioners, paediatricians, doctors in infant welfare clinics, health visitors, and others, but perhaps above all on its early recognition by parents and relatives, especially when there is a family history of squint. Delay in diagnosis and treatment is dangerous.

Fall-out and Strontium

After the explosion of the first hydrogen bomb in 1954 radioactive contamination of the environment and of human tissues reached measurable levels in many parts of the world. The long-term significance of fall-out is linked with deposition of strontium-90, a radioactive isotope with a half-life of 28 years. Because of its chemical affinity with calcium, this material is deposited in the skeleton, where it may be detected by chemical treatment and radioactive assay of bone samples obtained post mortem.

Work of this sort began in Great Britain in 1955[1] and is now conducted by two groups (one at the Capenhurst laboratories of the United Kingdom Atomic Energy Authority and one in Glasgow), who analyse more than 400 bone samples a year. The concentration of strontium-90 in bone is greater in children than in adults. The level of contamination rose to a peak in 1959 and declined slowly for three years before rising to another maximum in 1964 and 1965. The latest report[2] from the Medical Research Council, covering the first half of 1966, shows that levels of strontium-90 in bone continue to decline slowly, though remaining higher than at any time before 1964.

Arrangements for the analysis of human bone samples in the United Kingdom have been altered in a small but significant way. Until now the femur has been used in the British programme, but vertebrae have been analysed in most other countries. The difference is not important for infants, children, and adolescents, for whom little variation has been found in strontium-90 levels among the bones of the skeleton. In adults, however, the concentration of strontium-90 in vertebral bone is two to three times greater than in the femur. It has now been decided that the United Kingdom Atomic Energy Authority team (who receive an appreciable number of samples from adult subjects as well as from infants and children) will use vertebrae for analysis. The Glasgow group, whose work is confined mainly to study of samples from subjects under 5 years of age, will continue to analyse femora.

For the present, levels of strontium-90 in human bone do not give cause for serious anxiety in regard to radiation hazards, but valuable information is beginning to emerge from the study of the long series of results now available and from comparisons with other countries, where diet and weather conditions lead to differences in uptake of radioactive fall-out.

Coin-operated Vending Machines

The coin-operated vending machine answers a demand for quick meals and drinks at any hour of the day or night. Labour is minimal, being required only for maintenance and supplies. The machines are filled by the occupant of the land or premises on which they stand or by the company operating them. They may be either hired or purchased. If hired their maintenance is the responsibility either of the company loaning the machines or of those hiring them. Vending machines may be found in factories, hospitals, offices, and air, rail, or sea terminals, garages, sports grounds, exhibition halls, and also in streets and arcades of towns and cities. The food sold ranges from hot meals and sandwich or pie snacks to hot or cold drinks of many varieties.

The food is stored in an enclosed system, so that a simple cleaning process is essential to avoid the accumulation of stale food, particularly in powdered form, or liquid in parts of the machine invisible to the public eye. Many of the cold foods are perishable—for example, meat sandwiches, pies, and sausage rolls. Thus the temperature of storage is important and also the length of time the foods are held in the machine. The Food Hygiene Code of Practice No. 7,[1] of which M. Parry[2] has discussed the background, recommends a temperature of storage in accordance with the Food Hygiene Regulations[3]—that is, below 10° C. (50° F.) or above 62° C. (145° F.)—though these regulations apply only to food for immediate consumption in catering establishments. The Code of Practice gives no recommended time of storage for perishable products in vending machines, which in fact are acting as domestic refrigerators and should be operated at the appropriate temperature of 3–5° C. (37–41° F.). It has been reported[4] that machines vending perishable foods in the U.S.A. are required to hold those foods under refrigeration or alternatively above 140° F. (60° C.). In one district perishable foods and sandwiches with perishable fillings are required to be marked with the date of manufacture and permitted only 24 hours' storage in the machine. Perishable foods vended in the U.K. might be marked with the date of manufacture or a statement giving the final date for consumption. Machines should be sited away from the direct rays of the sun or suitable protection provided,[5] and only heat-treated milk should be used in vending machines.

---

[2] Parry, M., *Publ. Hlth Inspect.*, 1967, **75**, 369.

[3] Statutory Instruments (1960), *The Food Hygiene (General) Regulations*, 1960, Cmnd. 1601. H.M.S.O.

[4] Hughes, H. L., *Munic. Engng. Lond.*, 1967, **144**, 926.

[5] Skinner, W. E. D., *Roy. Soc. Hlth J.*, 1967, **87**, 19.

[6] Bailey, C. A., *Publ. Hlth Inspect.*, 1967, **75**, 306.

[7] Gibson, H. G., ibid., 1966, **75**, 121.

It is important that foods intended to be eaten hot should be maintained at temperatures above 145° F. (62° C.), as recommended in the Code of Practice. H. L. Hughes[4] reports that in the U.S.A. a microwave oven may be included in the range of vending machines to allow quick cooking of small articles of food provided by other machines. C. A. Bailey[6] describes incidents of chemical poisoning from vended fruit juices and recommends that occasional checks should be made for the metallic content of fruit juice vended from machines.

In the interests of public health there would seem to be need for close co-operation between the various sections of the food industry engaged in packaging and automatic vending and the public health authorities.[7] Moreover, as a precautionary measure firms intending to buy vending machines might be well advised to dismantle and reassemble the apparatus to check that it can be operated and cleaned in an efficient manner.

One Step Nearer?

According to the Treaty of Rome its provisions were to come into effect not later than 12 years from the signing of it in 1957. The treaty provides for free movement of doctors within the countries of the Common Market. The articles which deal with the matter are mainly article 48, which covers freedom of movement, and article 57, which refers to directives about mutual recognition of diplomas, certificates, and other qualifications, and the progressive removal of restrictions. To put these articles into effect certain adjustments in the conditions of practice and educational systems of the member countries will be required.

The Permanent Medical Committee of the European Economic Community, which, as previously explained,[1] was formed in 1956 with representatives from national medical associations of the member States and is a purely advisory body with no executive power, has made recommendations on these matters. These recommendations have been presented to the Commission—the standing administrative body of the European Economic Community—and last month the appropriate working party of the Commission met in Brussels to draft a directive on the subject. The working party, which is composed of civil servants, is also concerned with other professions—such as law, engineering, and architecture—and its directive should embody the plans for free movement of these as well as the medical profession. A draft should be presented by the end of the year to the Commission, whence it will go to the Council of the Ministers of the Six next year. It has to be unanimously approved by the Council and the European Parliament in Strasbourg and will then be referred back for ratification in the respective Parliaments of the member States. It could become implemented by January 1969.

The Permanent Medical Committee does not believe that this programme will give enough time. It thinks there is need for a delay of about five years to allow the various problems to be solved satisfactorily. In its view there are two major stumbling-blocks. Firstly, although some agreement has been reached in principle on the medical curricula of the member countries, there is a considerable difference in length and type of training for both graduation and specialization in each of the countries of the Six. Secondly, the social security systems in each country will require some harmonization. The medical administration of each country is closely linked with its social security system, and modifications may not be simple.

Opinion in Brussels is optimistic that Britain's entry to the Six may become a reality in about two years. Since new entrants are required to go through a transition period before full integration with the European Community, doctors here will have the opportunity of observing how matters are working out for their colleagues on the Continent, if the timetable envisaged by the Community's civil servants is fulfilled.

---

Elusive Popliteal Pulse

Fortunately in the majority of sites where we wish to determine the existence of an arterial pulse the vessel is near both to the surface and to the underlying bone. Thus the detection of the carotid, subclavian, brachial, radial, femoral, and foot pulses is easy. It is not so with the popliteal pulse. It is often essential to know whether the popliteal pulse is present or absent—for example, to distinguish a block of the lower femoral artery from one of the popliteal artery—yet many students, some of them postgraduate, have been heard to say that they have never felt it.

R. Ger[1] points out that the lower half of the popliteal artery is nearest to bone and skin as it lies behind the head of the tibia, and that this should be the standard point for palpating it. In fact there are three methods of palpating this artery, and the clinician may have to try them all before being sure that the pulse is absent. The commonest method is to grasp the upper end of the tibia with both hands—thumbs in front, fingers behind—with the knee slightly flexed. If the fingers are then moved from side to side they slip over the neurovascular bundle, which, once identified, can be fixed between the fingertips and compressed back against the bone. Occasionally it is easier to feel the artery higher up, behind the lower end of the femur, by hyperextending the knee joint with one hand pushing backwards on the patella, and placing the fingers of the other hand between the popliteal fossa and the bed. Both of these methods may be ineffectual in an obese person.

Probably the best and most certain way to feel the popliteal pulse is to have the patient in the prone position. The whole length of the popliteal fossa can then be palpated with the tips of the fingers of both hands. A pulse that cannot be felt in this way is surely absent. As with all clinical techniques, success comes from constant practice and, in the matter of palpating the popliteal pulse, self-discipline. A quick feel behind the knee is of no value. The approach must be slow, deliberate, and painstaking.

Personality Traits Associated with Different Chest Pains after Myocardial Infarction

R. R. H. LOVELL,* M.D., F.R.C.P., F.R.A.C.P. ; A. VERGHESE,* M.D., B.SC., D.P.M.

Brit. med. J., 1967, 3, 327–330

Most patients who have had an acute myocardial infarction later experience pain in the chest of one sort or another. Angina pectoris is the commonest pain, and one in or including the left anterior chest is the next commonest single entity. The factors which determine post-infarction pain are complex. Clinical observation suggests that they include mental ones. Angina pectoris is often induced by emotion, and left chest pain in patients with heart disease has long been associated with anxiety. If mental factors associated with pain after myocardial infarction could be defined, more might be learnt of the mechanisms causing the pains and it might be possible to prevent some of them.

The first difficulty faced in trying to relate mental factors to chest pains is that clinical judgements regarding the diagnostic category to which a pain belongs are often unreliable. This difficulty can be overcome if precise criteria are laid down for specified pain entities, and these criteria are sought by using standard questions which avoid the influence of the observer's bias. On this basis Rose (1962) proposed criteria for diagnosing angina pectoris in epidemiological studies. Extending this approach, we have recently classified pains occurring after myocardial infarction and have shown the reliability of the pain questionary on which the classification was based (Verghese and Lovell, 1966).

The second difficulty arises from the fact that clinical judgements about mental traits are no more reliable than they are about the nature of chest pain, and similar problems of definitions exist (Carstairs, 1963). Cattell and Scheier (1961) have commented: "Theory and therapy are in a confused state essentially because one cannot be quite sure what another is talking about when he says 'anxiety' or 'neurosis,'" and they see as an answer to this the placing of instruments for meaningful and exact measurements in the hands of the clinician. Various attempts have been made to develop such instruments, including personality inventories and methods for measuring physiological and biochemical reactions to standard stressful situations. We have recently described the use of the latter method in a study in which catecholamine excretion and sympathetic nervous responses after a standard mental stimulus were compared in patients who, having had a myocardial infarction, had been classified according to their subsequent experience of chest pain (Nestel *et al.*, 1967). We now describe attempts to measure personality traits in these patients.

Methods

The patients studied were those whose pain experience we have described previously (Verghese and Lovell, 1966). They were Australian- or British-born men, with an average age of 56, who had been in hospital with acute myocardial infarction. On discharge from hospital they had been admitted to a controlled trial of long-term treatments with anticoagulants. The diagnostic criteria for admission to the trial and the clinical characteristics of patients admitted have been reported elsewhere (Lovell *et al.*, 1964).

The main group of 106 patients was derived from 121 admitted consecutively to the trial, of whom three died before they could be studied, one was too muddle-headed, and 11 were missed because their clinical attendances did not coincide with questionary sessions.

With the use of the questionary appended to the previous report (Verghese and Lovell, 1966), all these patients were classified with regard to their pain experience after an interval of between six months and three years from their myocardial infarction and before other measurements were made. The pain categories defined were: angina pectoris, either as the only pain recognized or with additional pain ; left chest pain ; other pains ; and no pain.

All these patients were designated for measurements of personality traits. For this purpose two questionaries were used, the Eysenck Personality Inventory (E.P.I.) (Eysenck and Eysenck, 1964) and the Cornell Medical Index Health Questionnaire (C.M.I.) (Brodman *et al.*, 1949).

The E.P.I. consists of 57 questions and is intended to measure two dimensions of personality, neuroticism–stability and introversion–extroversion. According to Eysenck (1959) the dimension of neuroticism measures people's emotional stability. Neuroticism is the "general emotional lability of a person, his emotional over-responsiveness, and his liability to break down under stress." The dimension of introversion–extroversion measures people's sociability along a continuum from an extreme extrovert position reflecting a maximum degree of "outgoing, uninhibited social proclivities" of a person to an extreme introvert position reflecting a minimum of such proclivities. The inventory is designed so that neuroticism–stability and introversion–extroversion are measured as separate dimensions. This is confirmed in large-scale studies where the correlation coefficients between extroversion and neuroticism scores are found to be negligible.

The C.M.I. consists of 195 questions in 18 sections and was designed for use as an adjunct to the medical interview. The first 12 sections (A–L) are intended to reveal somatic symptoms, and the last six sections (M–R) are intended to reflect mood and feeling A high M–R score is said to discriminate neurotic patients from normals (Culpan *et al.*, 1960).

The following scores were calculated: (1) the neuroticism score (N score) from the E.P.I., (2) the extroversion score (E score) from the E.P.I., and (3) the number of "yes" responses in sections M–R of the C.M.I. (M–R score).

---

* University of Melbourne Department of Medicine, the Royal Melbourne Hospital Post Office, Victoria, Australia.

The patients were given the E.P.I. and C.M.I. forms together with a stamped addressed envelope when they paid a routine visit to the clinic. They were all aware that the clinic was concerned with research and they were told that their replies might help us to learn more about their diseases.

One of the designated patients died before he could be studied. From the remaining 105, 97 completed forms were received. Of the remaining eight, six were in the no pain group and two in the angina pectoris group.

Since physical constitution has been related from time immemorial to mental traits, some physical dimensions were measured in a subgroup of these patients. The subgroup was selected from among patients in the main group, on the basis that a comparison would be attempted between 10–15 patients in the angina pectoris only, the left chest pain, the other pains, and the no pain groups. All 10 patients in the left chest pain group agreed to participate in this extended study and four of the 12 in the other pains group refused. Of the first 15 patients in the angina pectoris group, designated by their consecutive attendances at the clinic, one refused and two were not used because they were thought to be too senile to take part in a mental-stress test associated with this part of the study (Nestel *et al.*, 1967). Of the first 14 patients similarly designated in the no pain group, one also refused and one was thought too senile. Thus there were 42 patients in the subgroup. The physical dimensions measured were: height, transverse chest diameter, weight, and the skinfold thickness at three sites. The transverse chest diameter was taken at the fourth intercostal space, midway between inspiration and expiration, by means of an obstetrics pelvimeter. From the chest diameter and the height the Rees–Eysenck body index was obtained, a nomogram (Hamilton, 1950) being used. The sites for the measurements of skinfold thickness were left subscapular, left triceps, and left umbilical, and from these the total body fat was calculated, the formula proposed by Edwards and Whyte (1962) being used.

Finally, in the subgroup of 42 patients, a clinical interview was conducted. Neither the pain categories to which the patients belonged nor their scores on the personality inventories were known by the interviewer at the time of the interview. The interview was of an ordinary psychiatric kind, the patients being encouraged to talk freely without much interruption. An item sheet was used, but only as a guide to direct the interview and to permit classification of the findings which emerged from it.

Results

Table I shows the number of patients in the different pain categories and their personality inventory scores.

TABLE I.—*Personality Inventory Scores*

Pain Category	No. of Patients	Scores (Standard Deviations)		
		E.P.I.		C.M.I. M–R
		E	N	
Angina pectoris only	28	9·6 (3·4)	10·7 (5·8)	8·9 (3·3)
Angina plus another type of pain ..	9	8·0 (4·3)	14·3 (4·6)	10·4 (8·3)
Left chest pain ..	10	11·6 (5·1)	14·2 (5·5)	11·3 (11·1)
Other pains	12	8·8 (3·9)	8·8 (4·6)	5·1 (4·3)
No pain	38	10·9 (4·1)	7·6 (4·2)	4·3 (4·5)

The mean E scores did not differ significantly between the groups. The N and M–R scores were highest in the patients with left chest pain and in those with angina who recognized more than one type of pain. The scores of those who recognized angina as their only type of pain, though not so high, were also greater than those of the other pains and no pain groups. Differences between means which were significant are given in Table II.

Scores reported for normal working-class and neurotic patient groups are shown for comparison in Table III. The mean N scores of the patients with left chest pain, of those with angina who recognized more than one type of pain, and of the neurotic patients were practically the same, while the mean N scores of the other pains, no pain, and normal groups were also very similar to each other. The same groups resembled each other in M–R scores also.

TABLE II.—*Difference in Scores Between Groups Which Were Significant*

Scores	Comparison	Difference Between Means	Significance
N	Left chest pain *v.* no pain	6·6	P < 0·01
	„ „ „ *v.* other pains	5·4	P < 0·05
	Angina only *v.* no pain	3·1	P < 0·05
	„ plus another type of pain *v.* no pain	6·7	P < 0·001
	„ „ „ „ „ „ *v.* other pains	5·5	P < 0·02
M–R	Left chest pain *v.* no pain	7·0	P = 0·05
	Angina plus another type of pain *v.* no pain	6·1	P < 0·05

TABLE III.—*Personality Inventory Scores of British Normal Working class and Neurotic Patient Groups**

Group	Scores (Standard Deviations)				
	E.P.I.			C.M.I.	
	No.	E	N	No.	M–R
British normal working-class	85	11·2 (4·4)	7·8 (4·8)	48	2·8 (3·4)
British neurotic patient	61	10·0 (4·3)	14·4 (5·5)	46	14·1 (10·0)

* The British normal working-class and neurotic patient groups were ones whose N and E scores were reported by Eysenck and Eysenck (1964) and others whose M–R scores were reported by Culpan *et al.* (1960).

Table IV shows the Rees–Eysenck index, the total body fat, and the ratio weight: height for the different pain categories. Differences between means which were significant are given in Table V. The left chest pain group had the highest and the angina group had the lowest Rees–Eysenck body index: that is to say, the former tended to be relatively narrow-chested in relation to their height. For total body fat and weight: height ratio the angina group had the highest and the left chest pain group had the lowest means.

TABLE IV.—*Body-build Indices*

Pain Category	No.	Means (Standard Deviations)		
		Rees–Eysenck Body Index	Total Body Fat in kg.	Weight (lb.) / Height (in.)
Angina pectoris*	12	94·8 (4·0)	21·0 (5·7)	2·56 (0·35)
Left chest pain	10	99·7 (5·5)	14·2 (4·1)	2·12 (0·27)
Other pains	8	95·7 (5·2)	19·8 (2·9)	2·40 (0·20)
No pain	12	94·7 (5·2)	19·1 (3·8)	2·37 (0·20)

* Recognizing only one type of pain.

TABLE V.—*Difference in Body-build Indices Between Groups Which Were Significant**

Indices	Comparison	Difference Between Means	Significance
Rees–Eysenck body index	Left chest pain *v.* angina pectoris ..	4·9	P < 0·05
	„ „ „ *v.* no pain	5·0	P < 0·05
Total body fat	„ „ „ *v.* angina pectoris ..	6·8	P < 0·01
	„ „ „ *v.* no pain	4·9	P < 0·01
	„ „ „ *v.* other pains ..	5·6	P < 0·01
Weight / Height	„ „ „ *v.* angina pectoris ..	0·44	P < 0·01
	„ „ „ *v.* no pain	0·25	P < 0·05
	„ „ „ *v.* other pains ..	0·28	P < 0·02

* The angina patients are those recognizing only one type of pain.

Table VI compares the indications of neurosis extracted from clinical interview data for each of the groups. A history of items such as marital disharmony, psychiatric illness in the family, unsatisfactory parent–child relations, and frequent change of jobs was found most commonly in the left chest pain group. Patients in this group also more commonly exhibited behaviour traits found in neurotic subjects. The total number of these indicators recorded in the left chest pain group was found to be significantly higher than in each of the other groups.

TABLE VI.—*Clinical Interview : Number of Patients in Each Pain Group Showing the Item Listed*

Items	Pain Category			
	Angina Pectoris	Left Chest Pain	Other Pains	No Pain
Parental lack*	4	5	1	5
Unsatisfactory parental relationship†	1	4	1	2
Psychiatric illness in the family	1	3	2	1
Marital disharmony	1	4	3	1
Position in school (studies) below average	2	3	1	1
Frequent change of jobs	1	3	0	1
Not satisfied with work	2	4	2	1
Perfectionistic	4	6	2	2
Cannot sit down and relax when there is no work	5	7	2	2
Fussy about tidiness and discipline	3	5	1	1
Not easy-going in everyday life	2	7	1	1
Clinical impression of being tense	2	4	0	1
Total items	28	55	16	19
No. of patients in each group	12	10	8	12

* Dead, separated for more than one year, or habitually absent from home.
† Relationship with one or both parents not happy.
Significant differences between numbers of items among patients in each group, tested by χ^2:
Left chest pain *v.* no pain ($P < 0{\cdot}001$).
,, ,, ,, *v.* other pains ($P < 0{\cdot}001$).
,, ,, *v.* angina pectoris ($P < 0{\cdot}001$).

Discussion

In interpreting these findings, the possibility that factors associated with the original acute episode of myocardial infarction may have varied between the groups, and perhaps have influenced the indices subsequently measured, merits consideration. There is no evident variation in such factors in this study. All the patients were men admitted to the same hospital with an acute illness fulfilling strict criteria of myocardial infarction, and subsequently supervised by the same small group of doctors in the same clinic. Furthermore, the severity of the acute myocardial infarction, as measured by laboratory indices and by the number of days spent in hospital (average 20), did not differ between the groups.

The inferences to be drawn from the findings must depend on the meaning of N and M–R scores in the situations in which they were measured and especially on the extent to which they may be influenced by physical illness. The E scores raise no problem in interpretation, since the groups did not differ in this trait.

The E.P.I. was developed from results of studies in clinically normal population groups. The N score has been conceived as an index of constitutional neuroticism, and a high score is found in neurotic patients (Eysenck and Eysenck, 1964). In normal subjects the N score appears relatively stable, the correlation coefficient of scores tested and then retested after 8 to 12 months being over 0.8 (Eysenck and Eysenck, 1964). However, the finding of Knowles and Kreitman (1965) that in neurotic patients the high N scores fell somewhat after treatment suggests that they may be influenced by environmental factors. The finding of McGuire *et al.* (1963), using the Maudsley Personality Inventory (M.P.I.) from which the E.P.I. was developed, that N scores did not differentiate neurotic from psychotic patients also suggests that the N score cannot be regarded simply as an index of constitutional neuroticism.

The possibility that N scores may be modified by physical illness has not been critically tested. Sainsbury (1960) found that patients attending a general hospital with a variety of physical illnesses had raised N scores as measured by the M.P.I. He interpreted the findings as showing an association between neuroticism and certain so-called psychosomatic conditions. Among these, coronary disease was listed as psychosomatic and herniated disc as possibly psychosomatic. He did not discuss the possibility, with which his findings are consistent, that certain sorts of physical diseases may themselves cause the N scores to rise. This possibility cannot be ignored in interpreting N scores in ill people.

Unlike the E.P.I., the M–R section of the C.M.I. was designed to reveal mood and feeling patterns in people attending for a medical interview. Its use in clinics dealing with organic diseases has been more extensively reported (Brodman *et al.*, 1949 ; Leigh and Marley, 1956 ; Culpan *et al.*, 1960), and the possibility that the emotional disturbances due to the nature of some physical symptoms may account for high M–R scores has been mentioned (Culpan *et al.*, 1960). Using a modified C.M.I., Rawnsley (1966) found that in physical disorders both physical and psychological mean symptom frequencies are raised.

High Neuroticism Scores

Our results show that after myocardial infarction patients who have left chest pain and also those who experience angina with some additional type of pain which is not necessarily in the left chest have, on two independent ratings, the highest scores for neuroticism. Their N scores are as high as those which have been found in neurotic patients (Eysenck and Eysenck, 1964 ; Knowles and Kreitman, 1965). Comparably high M–R scores are also found in neurotics (Leigh and Marley, 1956 ; Culpan *et al.*, 1960 ; McDonald and Mowbray, 1967). The finding of these high scores in the left chest pain group accorded with the finding in them on clinical interview of the frequent occurrence of features commonly found in neurotic patients. It also accords with the widely held clinical impression that patients who consult doctors complaining of this sort of pain are neurotic (Conner, 1930 ; Bourne, 1937 ; Wittkower, 1937 ; Schnur, 1939 ; White, 1951 ; Wood, 1956). The fact that the left chest pain group had features of body build which have been shown to be associated with the trait of neuroticism (Rees, 1944 ; Eysenck, 1947 ; Parnell, 1957) suggests that in them the trait is constitutional and was already present when they had their myocardial infarction. We lack information on body build in the patients with angina plus some other sort of pain, but their very high N or M–R scores suggest that they may fall in this same category.

The interpretation of the findings in the group whose only recognized pain was angina pectoris is more difficult. Their scores for neuroticism, while not as high as those of patients with left chest pain and angina plus some other sort of pain, were nevertheless above those of the no pain group. However, they did not differ significantly from the no pain group in features of neuroticism detected on clinical interview and they lacked somatic features associated with constitutional neuroticism, tending to be fat and heavy in proportion to their height.

The fact that the N and M–R scores of the other pains group did not differ from those of the no pain group shows that experience of chest pain is not inevitably associated with rises in these scores. However, some findings are consistent with the possibility that the scores may be influenced by the duration and frequency of pain experience. In the angina pectoris only group we found that the N and M–R scores of the patients whose pain had started before their infarct tended to be above those of the patients whose angina followed it, though the differences between the means of 1.5 and 2.5 respectively could have occurred by chance. The average frequency of the experience of pain was greater in the angina pectoris group (5 times a week) than in the other pains (1.9 times a week) and left chest pain (1.8 times a week) groups. The angina pectoris group were also apparently " iller " in the sense that a greater proportion of them had been prescribed drugs for treatment of cardiac failure or hypertension. The possibility is not therefore excluded that the raised N and M–R scores in the angina pectoris only group are consequences of the type, severity, and duration of the particular symptoms which they experienced.

An alternative possibility is that the angina pectoris only group had a higher than average degree of constitutional neuroticism before their infarcts and that the expected accompanying features of body build, evident in the left chest pain group, were absent perhaps because of a strong association between angina and mesomorphism. This possibility gains support from the finding of Ostfeld *et al.* (1964), in a prospective study, that indices of personality in men who later developed angina differed from those of men whose coronary disease presented as myocardial infarction. Ostfeld *et al.* found that the men developing angina had shown relatively high scores for traits of emotional lability and suggestibility.

Difficulties in Interpretation

The difficulties in interpreting the findings in the angina group reflect the need for further evaluation in ill people of methods currently used for measuring personality traits. But in whatever way the results of these attempts to study personality traits associated with chest pains are interpreted, it is clear from them that studies of mental factors in coronary disease must take account of the different pain experience of different patients. Coronary disease is not to be regarded as a single entity.

From the practical point of view we have been impressed with the frequency with which unnecessary invalidism after myocardial infarction tends to be associated with experience of left chest pain and of multiple chest pains. By the time patients actually complain of these pains they are often depressed. The findings reported here suggest that it might be worth while trying, early in convalescence, to identify patients with the high degrees of neuroticism which are associated with these particular pains. If the doctor responsible for guiding the patient's return to active life were forewarned, some of the disabling features of these pains might be prevented or at least recognized early and mitigated.

Summary

Ninety-seven men who had had a myocardial infarction were classified according to their subsequent experience of chest pain, in the following groups: angina pectoris, left chest pain, other pains, and no pain. Personality traits were measured in them by means of the Eysenck Personality Inventory for extroversion and neuroticism, and the M–R section of the Cornell Medical Index for neurotic symptoms. Indices of body build were measured in 42 of the patients who were also examined in an ordinary psychiatric interview.

Patients in the left chest pain group and those who experienced angina together with some additional type of chest pain had the highest neuroticism scores. The left chest pain group tended to be long and narrow in body build and to be the least fat. Patients recognizing angina as their only pain also had higher neuroticism scores than did the other pains and no pain groups, but in body build they tended to be fatter and relatively heavy for their heights. The other pains and no pain groups did not differ in any indices measured.

Because the left chest pain group had physical features recognized as being associated with constitutional neuroticism, this trait is regarded as constitutional in them, and its early recognition in the hope of preventing unnecessary invalidism is advocated.

The significance of the raised scores in patients with angina is discussed.

This study was supported in part by a grant from the National Heart Foundation of Australia and was made possible by the collaboration of the staff of the Royal Melbourne Hospital. We are indebted to Professor Brian Davies and Dr. Robert Mowbray for helpful comments.

Comparison between Three Radioisotope Methods for Measuring Iron Absorption

J. A. LUNN,* M.B., CH.B., M.R.C.P.ED. ; JOHN RICHMOND,† M.D., F.R.C.P.ED., M.R.C.P.
J. D. SIMPSON,‡ PH.D., B.SC. ; JOAN D. LEASK,§ B.SC. ; PETER TOTHILL,|| PH.D., B.SC., F.INST.P.

Brit. med. J., 1967, 3, 331–333

The present methods for determining iron absorption from the alimentary tract depend on the measurement by radioisotope techniques of iron retained in the body after oral administration. They vary in convenience and complexity, and sometimes require assumptions about iron metabolism for their interpretation.

The first, the "faecal recovery" method, was introduced by Dubach *et al.* (1948). In this method after a dose of iron-59 has been given by mouth the patient's stools are collected for several days until the excretion of radioactivity has stopped. The most important criticism of the faecal method is the difficulty of ensuring absolutely complete stool collections even from the most intelligent patients and in the best hospital circumstances.

The second, the "double isotope method" first described by Saylor and Finch (1953), makes use of two isotopes of iron, iron-55 and iron-59, which can be measured separately because of the different energies of their radiation. One isotope is given by mouth (iron-59) and simultaneously the other (iron-55) is bound to the patient's plasma protein and injected intravenously. After a suitable interval the ratio of the two isotopes in a blood sample gives a measure of absorption. It is necessary to assume that absorbed iron and parenterally administered iron are handled by the body in exactly the same way through the whole spectrum of iron disorder from iron deficiency to iron overload. Moreover, the separation of iron-59 and iron-55 demands very careful preparation and concentration of samples and complicated counting equipment.

The third, the "whole-body-counting" technique, has been applied by several workers (Price *et al.*, 1961, 1962 ; van Hoek and Conrad, 1961 ; Callender *et al.*, 1966). In this method iron-59 is given by mouth, and shortly afterwards the amount given is determined by external whole-body counting of radioactivity. After 10 to 14 days, when unabsorbed iron has been excreted, the amount of iron retained is determined by a further external whole-body measurement. Of the three methods this can be seen to be much the most convenient for the doctor and the patient. However, it is necessary to consider the possible change of efficiency of counting between the first and the last measurement. In the first, the "100% measurement," the iron is mainly in the alimentary tract, but in the second there might be considerable variation in its distribution in the body, being mainly in the circulating blood in a patient with severe iron deficiency or mainly in the body stores in a patient with refractory anaemia. The whole-body counters employed for this type of study have usually been expensive instruments of high sensitivity and low background, designed to measure levels of natural radioactivity and small burdens of accidental contamination.

These three main radioisotope measurements of iron absorption have been compared simultaneously in a series of patients. No attempt has been made to evaluate the amount of iron absorption in relation to other aspects of iron metabolism, but rather to see what correlation existed between the three methods over a range of haemoglobin level, serum iron, and stainable marrow iron. The main purpose of the present study was to assess a simple and inexpensive apparatus of low but adequate sensitivity for whole-body counting.

Material and Methods

Iron absorption was measured in 17 patients. They were inpatients in the Royal Infirmary, Edinburgh, and at the time of the study they all had normal bowel function and none showed occult bleeding from the alimentary tract. The patients were in wards where collection of excreta is standard practice for metabolic studies, and the need to be most careful in the complete collection of stools was emphasized to the patients and nursing staff for this particular investigation.

Routine examination of peripheral blood was by methods described by Dacie and Lewis (1963). Serum iron levels and total iron-binding capacity were determined as described by Ramsay (1957). The iron content of sternal marrow aspirate was assessed by a staining technique ; the method is given by Richmond *et al.* (1956). The amount of iron has been recorded as absent (O) or present in the range one plus to three plus (+ to + + +). During each study all stools collected were examined for blood by the Haematest method.

Measurements of Iron Absorption

The first five patients (Cases 1–5) were given 10 μCi of iron-59 orally in the form of ferric chloride (specific activity in the range 3–15 μCi/μg.) in a standard breakfast (Pirzio-Biroli *et al.*, 1958) containing 7.5 mg. of food iron. The remaining 12 (Cases 6–17) received the same amount of iron-59 in the fasting state, together with 10 mg. of carrier iron and 50 mg. of ascorbic acid. The conditions of administration of iron were changed to produce a wider range in the amount of iron absorbed for the purposes of comparison between the methods.

Iron-55 (specific activity in the range 1–4 μCi/μg.) was incubated with the patient's plasma or donor plasma as described by Veall and Vetter (1958), and 60 to 90 minutes after the iron-59 had been taken orally iron-55-labelled plasma containing approximately 20 μCi of iron-55 was injected intravenously.

Faecal Recovery Method

Measurements of stool radioactivity were made in a counter consisting of a ring of Geiger–Müller tubes. Some stool samples were also assayed with a scintillation counter and good agreement was obtained.

Double Isotope Method

Blood samples taken at intervals of three to four days and on the same day as the final whole-body measurements were used to determine the ratio between the orally and intravenously administered isotopes. Iron was extracted from the washed red cells (W. N. M. Ramsay *et al.*, to be published) and electroplated on copper discs for counting.

Isotope separation was achieved by the use of two counters. Firstly, the radioactivity of iron-55 was measured by a xenon-filled proportional counter fitted with a beryllium window (Twentieth Century Electronics Ltd., Type PX 130/Xe), which largely absorbs the iron-59 β-rays but admits a reasonable proportion of the low energy *x* rays from the iron-55. Pulse height analysis enabled the iron-55 to be counted with an estimated efficiency of 6% and only 0.2% efficiency for iron-59; the background count rate was in the range of 0.3 to 0.7 count per second.

The radioactivity of iron-59 was then measured with an end-window Geiger–Müller counter in an anti-coincidence shield (Panax type LC/5). A platinum filter 0.015 mm. thick reduced the effect of the *x* rays of iron-55 to give counting efficiencies of 5.3% for iron-59 and 0.001% for iron-55. The background count rate was approximately 0.04 count per second.

The absorption of orally administered iron-59 was then calculated as follows:

$$\% \text{ absorption} = \frac{{}^{59}\text{Fe activity in blood}}{{}^{59}\text{Fe activity administered orally}} \times \frac{{}^{55}\text{Fe activity administered i.v.}}{{}^{55}\text{Fe activity in blood}} \times 100$$

To reduce statistical errors to a minimum long counting-times were necessary with both techniques. With the proportional counter, counting for 1,000 seconds gave approximately 10,000 counts, while counting for about 60 minutes was necessary to achieve a similar number of counts with the end-window counter. A separate standard for each isotope was prepared by adding known amounts of radioactivity to a sample of haemolysed red cells taken from the subject before the test. The standard red cells were then digested and electroplated in the same way as the blood samples.

The accuracy of the measurement depended on the similarity of recovery of radioactive iron for each standard. The quantitative recovery of added iron is easier than that of haemoglobin iron, and this consistency was checked in supplementary experiments.

Isotopic contamination of the solutions administered was found to be negligible.

Whole-body Counting Method

Whole-body iron-59 radioactivity was estimated with a single sodium iodide crystal, 12.5 cm. in diameter and 9 cm. in depth. The background count rate was reduced by means of a 2.5-cm. thick lead shield. This consisted of a plate 30 cm. long and 27 cm. wide, through which the crystal protruded, and sides 16 cm. high, forming an inverted U-shape. The shield was designed to accept radiation from the whole body without interference and to provide the maximum reduction in background count rate for a given amount of lead. At the energies used with the iron-59 studies the background count rate was approximately halved.

Measurements were made under integral bias conditions above 1 MeV to include both the 1.1 and 1.3 MeV photopeaks of iron-59; this gave a background count rate of approximately 50 counts per second. Counting was performed in two ways: firstly, with the patient in a sitting position in a reclining chair, and, secondly, with the counter placed at different points over the patient lying on a horizontal couch.

Measurements over the couch were made with a crystal-to-couch distance of 50 cm. and with the crystal vertically above positions 25, 75, and 125 cm. from the top of the head in each case. Counts were repeated in both the supine and the prone positions with the arms held by the sides. The sum of the six counts was then used as an estimate of the total body radioactivity. After a dose of 9 μCi the mean count rate in these six positions was approximately 360 counts per second, and a total patient counting-time of 600 seconds was used.

Only one 200-second count was required when using the chair geometry, in which the subject reclined with the chest at about 17 cm. from the nearest part of the crystal and with most of the body, except the head and the lower parts of the legs, positioned roughly in a 40-cm. arc around the centre of the crystal. A corresponding count in this arrangement after a 9 μCi dose gave approximately 650 counts per second.

The initial count on each patient was made four hours after the administration of iron-59, and this result was taken as the 100% retention value. The final absorption was estimated by re-counting between 14 and 20 days after the initial count, at which time the retention has reached a constant level (Schiffer *et al.*, 1964); this observation was verified on several patients by making serial measurements. To allow for any variation in counter sensitivity, a standard iron-59 source in a 5-litre polyethylene container was counted before and after each set of measurements. As the patient himself may modify the background count rate a count was made with him in position before the administration of the isotope, so that subsequent background measurements could be corrected for this.

The main advantage of the couch geometry is that it minimizes the effects of isotope distribution in the body on the efficiency of counting. These effects were studied by measuring the response of the counter to a small source as it was moved in different positions in a tank of water 20 cm. deep. Results showed that the effect of distance of the source from the crystal could be almost eliminated by counting from both sides of the tank and adding the two count rates. Allowance was made for the effect of isotope distribution in the patient by counting in both the prone and the supine positions.

Results

The main haematological data and the estimation of iron absorption obtained by the three methods in each of the patients are summarized in the Table.

Routine Haematological Data and Iron Absorption

Case No.	Haemoglobin (g./100 ml.)	Mean Corpuscular Haemoglobin Concentration (%)	Serum Iron (µg./100 ml.)	Total Iron-binding Capacity (µg./100 ml.)	* Marrow Iron	Iron Absorption Per Cent. Administered

*Arbitrary scoring of marrow iron: 0, + + + + + + (—, result not available).

Though a good correlation was obtained in the whole-body counting method between the sitting and lying positions ($r = +0.994$, $P < 0.001$, $n = 16$), the estimate of absorption for the sitting posture was much higher than for the lying position in four patients and exceeded 100% in two.

There was a high correlation ($r = +0.987$, $P < 0.001$, $n = 16$) between percentage iron absorption measured by whole-body counting in the lying position (y_1) and the double isotope method (x); these data are shown in Fig. 1. The regression equation of y_1 on x is given by $y_1 = 1.02x - 2.41$. The slope of this is not significantly different from 1.00 and the intercept is not significantly different from zero—that is, the regression line is not significantly different from the line of identity.

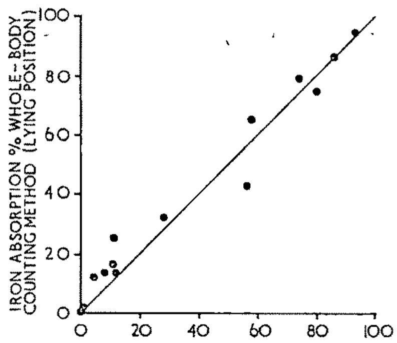

FIG. 1

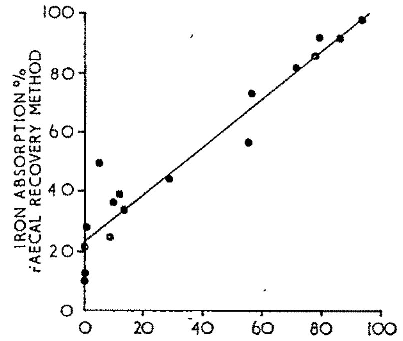

FIG. 2

FIG. 1.—Relation between iron absorption as measured by the double isotope method and the whole-body counting method (lying position). FIG. 2.—Relation between iron absorption as measured by the double isotope method and the faecal recovery method.

The correlation ($r = +0.961$, $P < 0.001$, $n = 17$) between the results of the faecal recovery method (y_2) and the double isotope method (x) was also good (Fig. 2). However, the regression equation for y_2 upon x is given by $y_2 = 0.798x + 23.5$. The regression coefficient of this line is significantly different from 1.00 ($0.001 < P < 0.01$) and the intercept is significantly different from zero ($P < 0.001$). Hence this regression line differs significantly from the line of identity.

Discussion

It is shown that the whole-body counter used with couch geometry gave results in good agreement with those from the double isotope technique. The sitting position led to rather poorer agreement, presumably owing to redistribution effects.

There was considerable discrepancy between the faecal recovery method and the other two methods, especially at the lower levels of iron absorption. This difference is believed to be due to incomplete faecal collections, despite full co-operation from nursing staff and patients. A similar result was obtained by Pitcher *et al.* (1965). Callender *et al.* (1966), in comparing results obtained by the whole-body counting method and faecal recovery method, believed that stools were lost by 16 of their 54 patients.

Callender *et al.* (1966) concluded that a whole-body counting technique with the use of a double detector system and travelling motor-driven couch was a very reliable and convenient way of measuring iron absorption. The present study, in which a very simple whole-body counting system was employed, confirms this view. Counts made in three positions from each side of the patient are combined, and this seeems to overcome inaccuracies from redistribution of isotope. Each measurement of whole-body radioactivity took about 15 minutes; a further 15 minutes was required for the counting of background radioactivity and a standard. The apparatus cost approximately £750, excluding the scaler.

Summary

A simple inexpensive whole-body counting technique for iron absorption in which radioactivity was measured in three positions with the patient prone and supine is described. It gave results which correlated well with the double isotope method in 16 patients who showed a wide range of haemoglobin level, serum iron, and stainable marrow iron.

Only two measurements on the patient were required, each taking about 15 minutes.

The faecal recovery method for iron absorption, which was used simultaneously, showed poor agreement with the whole-body counting and double isotope techniques. The discrepancy was believed to be due to incomplete stool collections, despite attempts to avoid this.

We wish to thank Dr. D. L. Gardner for estimation of marrow iron and Dr. W. N. M. Ramsay for assistance and advice and the determinations of serum iron. We are grateful to Miss A. A. McKay, Miss I. Martin, and Miss M. McArthur for their technical assistance.

Epidemiological Aspects of Squint

A. M. ADELSTEIN,* M.D., D.P.H.; JOHN SCULLY,† M.B., CH.B., D.P.H., D.O.M.S.

Brit. med. J., 1967, 3, 334–338

This paper deals with squint in children diagnosed in two clinics—the Manchester Royal Eye Hospital and the Ophthalmic Clinic of the Health Department, Salford—discusses some demographic and social factors associated with squint and particularly with non-central viewing. It also confirms the observations of Scully and Naylor (1961)—namely, that non-central viewing occurs frequently (in about 22% of cases of squint); that it is more prevalent in younger children, particularly in those who have remained untreated for long periods; and that it appears very commonly in children with a high degree of anisometropia. We are now more confident about the estimates of these interrelationships because of the larger sample of cases we are able to present. Non-central viewing is shown to be more common in boys; and the possible associations between squint, season of onset, and recent infection are discussed.

The records presented are of children between the ages of a few months and 10 years examined by one of us (J. S.) at the above-mentioned clinics during the period October 1960 to March 1965.

Patients at the Manchester Royal Eye Hospital are referred by doctors in the area of the Manchester Regional Hospital Board. However, it is not possible to define the population from which patients would necessarily be referred. Patients at the Ophthalmic Clinic of the Health Department, Salford, are referred by the Maternal and Child Health Service and the School Health Service of Salford and also by practitioners. We are confident that very few cases in Salford came from other clinics, and we can therefore use these data to estimate rates of squint in the community.

The method of examination has already been described (Scully, 1961a). The history, taken from the parent or other informant, includes date of birth, family history, date when the squint began, and possible precipitating factors. The physical examination includes ocular movements, cover test, refraction, examination of fundus, and estimation of fixation with aid of the visuscope.

Presentation of Figures

In the papers already mentioned it has been shown that the time which elapses between the onset of the squint and its ascertainment was related to non-central viewing. Hence, mothers of all the patients referred to in this paper have been carefully questioned regarding the date of onset of the squint. The age at onset or the interval between onset and ascertainment is given in the Tables as one factor. We realize that memory and observation will sometimes be at fault and that the time when a squint began may not be easy to define; nevertheless, age at onset and time between onset and ascertainment are useful criteria. Because of the inevitable error introduced by relying on the observations and memory of the mothers we also refer to the age at examination. However, in a few of these cases the information was destroyed, and some Tables therefore show slightly smaller numbers.

Incidence of Squint

Table I shows the numbers of boys and girls diagnosed with squint in each year of age at the two clinics. Boys outnumber girls slightly. Since there is no defined group of people from which this hospital draws its patients it is not possible to calculate rates of squint. But if we assume that age does not determine whether a case will be referred here or elsewhere we can examine the relative incidence at various ages. The trend of distribution by age is similar in boys and girls. The highest incidence is at age 2 years, followed by ages 3, 4, 1, and 5 years successively.

TABLE I.—*Number of Cases of Squint by Age at Ascertainment, Sex, and Place of Examination*

Place of Examination	Sex	Age at Examination (years)							Total
		<1	1–	2–	3–	4–	5–	6+	
Manchester Royal Eye Hospital	Boys	47	211	365	315	222	115	91	1,366
	Girls	38	201	308	284	206	108	104	1,249
	All	85	412	673	599	428	223	195	2,615
Salford Health Department Clinic	Boys	10	49	54	40	54	37	41	285
	Girls	5	25	56	52	44	37	34	253
	All	15	74	110	92	98	74	75	538

Table II shows the cases of squint in boys and girls according to age at onset. The distribution of cases by age at onset is, of course, different from that of age at ascertainment, though in both categories the highest numbers are of children aged 2 years. However, about 16% of the squints are reported to have begun in the first year of life and relatively few after the fifth year.

Interval Between Onset and Examination of Squint

We have examined the distribution of intervals between onset and ascertainment in categories of three months, but for purposes of discussion we include in Table II the proportion of cases ascertained within one year. In the Manchester data, for both boys and girls, the smallest percentage and therefore the longest average delay occurs when the age of onset is

TABLE II.—*Number of Cases of Squint and Percentage Ascertained within One Year After Onset (in parentheses) by Age at Onset, Sex, and Place of Ascertainment*

† Senior Hospital Medical Officer, Manchester Royal Eye Hospital.

under 1 year. The percentage of cases ascertained within one year of onset tends to rise as the age at onset increases, and after the age of 2 years more than 80% of cases are ascertained within one year. In the data from Salford the trend of the length of interval between onset and ascertainment is much the same as in the Manchester data, though somewhat irregular owing to relatively smaller numbers.

The differences between the sexes with respect to the interval between onset and ascertainment may now be considered. The Manchester data show that when the age at onset is under 1 year a higher percentage of boys than of girls are ascertained within one year, and when the age at onset is after 1 year the girls have the shorter interval—that is, the percentage of girls ascertained is higher than that of boys within one year of onset for each age except for age 2. The differences, however, are small and attain statistical significance ($P<0.05$) in only one age group. The Salford data show the same trends except that in boys ascertainment is quicker when onset is in the first two years, and only later is the position reversed.

Type of Squint

The number of cases diagnosed in the Manchester Royal Eye Hospital according to the type of squint and the percentage of each type at each age group of onset are shown in Table III. (The number of children at Salford was too small for meaningful examination in these categories.)

TABLE III.—*Number of Cases by Type of Squint, and Percentage of Each Type by Age at Onset (Manchester)*

Type of Squint	Age at Onset (years)								No.
	<1	1–	2–	3–	4–	5–	6+	All Ages	
Right convergent squint	22·7	32·5	33·9	44·0	39·9	40·5	46·5	35·2	950
Left „ „	31·3	40·4	43·5	37·6	48·6	41·2	33·7	40·0	1,078
Alternating „ „	37·7	22·2	18·8	15·2	10·0	15·1	15·8	20·5	553
Right divergent „	2·5	1·2	0·8	0·2	—	0·8	—	0·9	25
Left „ „	1·9	1·6	1·4	1·0	0·6	—	3·0	1·3	36
Alternating „ „	3·9	2·1	1·6	2·0	0·9	2·4	1·0	2·1	56
Total number	432	569	639	500	331	126	101		2,698

The overall total shows that convergent squint is more common on the left side than on the right (40% and 35.2% respectively). As the age of onset increases the percentage of alternating squints diminishes—from 38% when the onset is in the first year to about 15% after the age of 3.

Central Viewing According to Age at Onset, Interval Between Onset and Diagnosis, and Sex of the Child

When the child does not co-operate a decision on central viewing cannot be made, and it is not surprising that the proportion of cases in which no decision is arrived at is larger in younger children. Among the Manchester children whose squint began in the first year of life 47% of boys and 44% of girls could not be diagnosed for fixation. Most of these children were, of course, examined before the age of 2. The proportion of cases not diagnosed for fixation diminishes as the age of onset increases, and when the onset occurs after the age of 4 hardly any cases remain undiagnosed.

Table IV shows the percentage of children with non-central viewing (among those cases in which a decision on central viewing could be made) according to age of onset, interval between onset and diagnosis, and sex. The association of each of these factors with non-central viewing can be examined independently.

Data from Manchester

Non-central Viewing and Interval Between Onset and Diagnosis.—The percentage of children with non-central viewing increases as the interval between onset and diagnosis increases; the trend is present in each age of onset and in both sexes.

Fixation and Age at Onset of Squint.—This relation is best examined among those children in whom the interval between onset and ascertainment was less than six months—that is, those represented in the first row for each sex in Table IV. These include most of the cases of squint, and the distribution of delay is likely to be similar within each group by age at onset. Among these children non-central viewing is most frequent in those with the youngest age at onset, and the rate decreases progressively as the age at onset increases. In each section of the Table there is a clear difference between the group with the youngest onset age and that with the oldest. When the delay between onset and ascertainment is 7 to 24 months the gradient of the percentage of non-central viewing is not distinct in each of the two rows, but there is a clear difference in proportion of non-central viewing between the children with the youngest and those with the oldest age at onset. This trend of decrease of non-central viewing with increasing age at onset does not emerge in the group showing the longest interval between onset and ascertainment—more than 25 months. However, it seems reasonable to suppose that the different trend has arisen because in this group there is a considerable difference between the average intervals in the three groupings of age at onset; of those children whose onset age is below 2 some have had a comparatively long delay, whereas in those in whom the age at onset is over 4 years the interval is short. The cases are too few in number for a more detailed analysis of this open-ended category.

Non-central Viewing According to Sex.—The boys have a higher proportion with non-central viewing than the girls in each category of age at onset and in each category of interval between onset and diagnosis (except one in which the numbers are small). Thus, on examining the column which refers to onset under 2 years of age and comparing the data of the boys with those of the girls, in each category of interval we have the following comparisons of pairs of percentages: 26.7, 16.5; 39.2, 26.9; and 45.1, 28.1. In general the Salford data follow the same pattern, though there are exceptions which are to be expected because of small numbers. Table IV presents the cases according to age at onset, and, since they are actually examined at varying times after onset, the data are presented in Table V with age at diagnosis as the variable in place of age at onset. This Table shows that two factors—interval after onset and sex—are, as shown previously, independently related to the frequency of non-central viewing. However, age at ascertainment, unlike age at onset, is not related to the frequency of non-central viewing.

TABLE V.—*Percentage of Children with Non-central Viewing According to Age at Diagnosis, Interval Between Onset and Ascertainment, and Sex. (The Number of Children with Squint in Whom a Diagnosis of Fixation was Made Shown in Parentheses)*

Anisometropia

The meridian with the greatest refractive error in each eye was considered and three categories are described: (1) patients with less than one degree of difference between the greatest meridian of the two eyes, (2) those with one to two degrees, and (3) those with more than two degrees of difference.

There is no indication of the frequency trend of these categories of anisometropia by sex or age at onset, the overall figures being 82% with less than one degree, 13% with 1–2 degrees, and 5% with more than two degrees among the 2,698 children examined at the eye hospital, and 82, 11, and 7% respectively at Salford.

Anisometropia and Non-central Viewing.—The relation between these attributes can be seen in Table VI for those cases in which fixation was determined. There is a regular increase in the percentage of children with non-central viewing from those with less than one degree of anisometropia (23% in boys and 13% in girls) to those with two or more degrees of anisometropia (70% in boys and 60% in girls).

TABLE VI.—*Number of Boys and Girls with Squint by Category of Anisometropia, Showing the Percentage of Non-central Viewing in Each Category*

Sex	Category of Anisometropia	No. of Children	Percentage with Non-central Viewing

Girls ..	No anisometropia	846	13·5
	1+ degrees	133	28·6
	2+ „	58	60·3
	Total	1,037	18·0

Social Class

An attempt was made to classify the children according to the social classes defined by the Registrar General and from the fathers' occupation. However, entirely suitable data are not available against which to compare the findings, since the social class distribution of children need not be similar to that of adults (depending on the marriage and fertility rates of their parents), and because we do not know the population at risk with reference to the Manchester Royal Eye Hospital. In addition we are not confident that the records are accurate regarding some subdivisions of occupations.

Bearing in mind these problems, we have calculated the expected number of children in the various social classes by using as the basic distribution the married women of the South-east Lancashire conurbation as shown in the report of the 1961 Census, and have adjusted these by the fertility rates. In both the Salford clinic and the Manchester Royal Eye Hospital there is a relative shortage of managerial and professional classes, except that in Manchester Royal Eye Hospital employed professional workers are in excess of those self-employed. These findings may be explained if more of the affluent classes are referred to private consultants, with the exception of workers in medical institutions whose children tend to be referred to the Manchester Royal Eye Hospital.

The other large disparity between the expected and observed numbers concerns the class of unskilled workers (socio-economic group II). About 11% of the children in the eye hospital are to be expected from this group, but there are 19%; in the Salford clinic the respective figures are 13.6 and more than 27%. In both samples the distribution differs significantly from the expected.

Season of Onset and Infections

The numbers of cases according to the month in which the squint appeared, as stated by the mothers, are shown in Table VII. The mean number per day in each month allows for difference in the length of month. A seasonal pattern emerges with a high peak of onset in January and a trough in June. The difference between the observed and expected numbers of cases, if there were only chance differences between the months, are highly significant (P<0.001).

TABLE VII.—*Frequency Distribution of Squint by Month of Onset (as Reported) Compared with Expected*

Month of Onset	No. of Cases		
	Observed	Expected	Mean per Day, Observed
June	221	259·1	7·37
July	233	267·8	7·52
August	250	267·8	8·06
September	221	259·2	7·37
October	270	267·8	8·71
November	258	259·1	8·60
December	305	267·8	9·84
January	389	267·8	12·55
February	269	241·9	9·61
March	289	267·8	9·32
April..	224	259·1	7·47
May	224	267·8	7·23
Total..	3,153	3,153 0	8·64

$\chi^3 = 93{\cdot}61$. d.f. = 11. P < 0·001.

These figures suggest that the squints tend either to occur or to be noticed for the first time during January and December, or that the informants (and the doctors) are more inclined to choose January or December. If illness plays a part in the presentation of squint or in noticing it, the figures could be explained by the increase of upper respiratory infections during these months. We were unable, however, to find any association between the particular seasons involved and the epidemics of measles in Manchester.

In each case of squint a question was asked about the occurrence of an illness in the four weeks preceding the onset. About 9% (230) reported that the child had measles, and an additional 15% (399) reported some other type of infection. Among those cases with a history of infection there is a similar increased incidence of squints in January as there is among the children with no history of infection.

Discussion

There are noticeable differences between published estimates of the incidence of squint (Nordlöw, 1964), and for a number of reasons some degree of variation is to be expected. There is evidence that squint is related to the development of the foetus and infant. Thus brain injury, spasticity, prematurity, mental deficiency, and other factors identified with social class have been shown to be relevant (Miller *et al.*, 1960 ; Nordlöw, 1964 ; Chief Medical Officer of the Department of Education and Science, 1966). If comparisons of incidence between populations are made, variations between these factors must be considered. In addition, the method by which the squints are ascertained may vary. For example, the data may be derived from routine medical services or from special surveys. If the data depend on routine services they will reflect variations of local practice, particularly in the delay between onset and ascertainment. Prospective studies would yield the most accurate estimates of rates of onset of squint by age, because retrospective methods rely on the observations, memory, and attitudes of the mothers. The only reasonably extensive prospective study of which we are aware is part of the well-known study of child development in Newcastle upon Tyne (Miller *et al.*, 1960), which revealed 40 cases of squint. This number represented 4.7% of all children up to the age of 5 years, and the authors quoted another survey showing 5% prevalence among children entering school in Newcastle between 1947 and 1952.

Nordlöw (1964) published a comprehensive survey of routinely ascertained cases in a defined area in Sweden. He estimated that a cohort of nearly 6,000 children at birth would develop, by the age of 6 years, 242 cases of squint—that is, 4.03% (or 2.6% of constant divergent squints). Let us consider our data from the Salford clinic as though they were almost complete ascertainment ; by adding the mean annual incidence rates of squints ascertained during each year of age-grouping we reach an approximate prevalence rate of a particular age. This works out as 4.3% at the age of 6, and is expected to be a slight underestimation of the actual state, since a small number of children would be referred elsewhere.

The assessment of the relative incidence of squint by age at onset is also variable. Nordlöw states that "retrospective information would be influenced if a long time elapsed between the onset of the squint and the initial examination." He found 52% with histories of less than one year, whereas in our data more than 75% are in this category. Comparison of the rate of onset by age shows that the pattern in his data differs from ours. Nordlöw reported that approximately 38% of the squints began in the first year of life, and in the ensuing consecutive years the percentages were 20, 14, 16, 7, 1, and 1 ; thus the highest proportion is in the first year, and then there is a decline year by year. In our data (similar in Manchester and Salford) the largest number of cases are reported to have begun in the third year of life (23.7% in Manchester), and slightly lower numbers in the second and fourth years (21.1% and 18.5%) ; then follow the first year, the fifth year, and the sixth year, after which hardly any cases occur.

In this respect the data from Newcastle—which, as mentioned above, have been gathered prospectively—resemble our data much more than Nordlöw's. In essence the survey method in the Newcastle study comprised regular visiting of a representative group of families. The percentages year by year were 5, 27, 25, 25, and 17. (The sampling errors are considerable.)

The surveys mentioned, and others, as pointed out by Nordlöw, divide into two characteristic patterns of distribution by age at onset of squint. First, those such as ours, in which the onset is most frequent between the ages of 1 and 4 years ; and those, such as Nordlöw's, in which the onset is commonest in the first year and then diminishes progressively. Even allowing for the fact that different surveys adopted different definitions of squint these patterns are quite distinct.

In attempting to explain the difference between the two patterns of incidence of onset of squint, a number of factors can be invoked, but they would hardly seem to be sufficient. Important differences between surveys, in addition to the variations between definitions of what constitutes a squint and its beginning, are possibly due to selection of cases ; in some instances those with an early onset, being younger, may be referred to one type of clinic and those with late onset to another. Selection may involve cases with associated defects such as brain injury or subnormality. Our data do not include certain categories of handicapped children, and therefore the percentage of squints which began in the first year of life would be deficient in our figures ; but this could by no means account for the large disparity in patterns of onset.

Another possible cause for the difference is that in those populations with a higher incidence the excess might occur in one particular age rather than another. For instance, if, say, in Manchester the overall rate of squints at 6 years of age was 5% and in Sweden 3%, the excess 2% if distributed mainly in the second to fourth years could account for the different patterns of onset described.

Non-central Viewing

Non-central viewing is a serious consequence of squint. In previous papers Scully (1961a, 1961b) has pointed out the association between non-central viewing and age at onset, interval between onset and ascertainment, and degree of anisometropia. We confirm these associations.

The influence of the time interval after the onset is particularly marked, so that when the delay is more than two years rates of non-central viewing are high, reaching even 70% among this group of boys in Salford. High degrees of anisometropia also are associated with non-central viewing, those children with more than two degrees of anisometropia having more than 60% with non-central viewing.

A surprising finding is that boys have more non-central viewing than girls in each category defined by age and interval and also in each category of anisometropia. In the Manchester data the boys have 27.9% and the girls 18% of non-central viewing, overall. We have no explanation for this difference between the sexes. It is not apparent that this difference could arise because parents delayed medical care for boys, and, in addition, subsequently volunteered a spuriously shorter history. This is unlikely, since the actual distribution of cases by age at examination is alike for each sex ; and in Salford most of the cases do not depend entirely on the mother's intervention, but are referred by the School Health Service or the Maternal and Child Health Service. The differences in the frequency of non-central viewing between the sexes must be taken as found. The fact that the proportion of children with non-central viewing diminishes as the age at onset increases suggests that non-central viewing may be a failure of integration of the various components of vision, since these would tend to improve with age. There are other functions which show higher rates of failure in boys ; for example, boys have higher rates of enuresis and of dyslexia. Dyslexia has been shown by Birch and Belmont (1966) to be associated with auditory-visual integration.

Season

The seasonal pattern of onset is quite distinct ; we have discussed some sources of possible error, but do not think that this clear pattern could be due to these errors. Since the pattern is similar among children who are reported to have had no infection and those who have had infections in the four weeks before the alleged onset, overt infection does not explain the trend. We can only speculate on factors such as subclinical infections, or length of daylight.

Summary

We report an analysis of 3,243 cases of squint examined at a health department clinic and an eye hospital. The estimated prevalence of squint at the age of 6 years is 4.3%, similar to estimates in other surveys in England. Incidence of onset is highest in the third year of life, and, if this distribution reflects the incidence in the community, it represents one characteristic pattern of distribution. Another pattern has been described in which the highest rate of onset is in the first year and diminishes rapidly thereafter. Non-central viewing occurs in 23% of the cases of squint in which this function could be assessed. Non-central viewing is much more frequent in boys, in children in whom the onset is early, in those who have had the squint for a longer period, and in those with high degrees of anisometropia. There is evidence that squints begin more often in winter, with a peak incidence in January.

We are indebted to Mrs. Anne Fish for her painstaking and careful handling of the data, and to Professor C. I. Phillips for his advice. We wish to thank the surgeons at the Manchester Royal Eye Hospital for making available for examination cases under their care.

Progestin Therapy of Breast Cancer: Comparison of Agents

BASIL A. STOLL,* M.R.C.S., F.F.R.

Brit. med. J., 1967, 3, 338-341

Over recent years many synthetic orally active progestational agents have been introduced to clinical practice. The multiplicity of such agents presents a problem of choice to the clinician considering progestin therapy in breast cancer. A similar problem applies also to uterine cancer. Various authors, each using a different progestin, have reported their results in small series of breast cancer cases (Jonsson *et al.*, 1959 ; Lewin *et al.*, 1959 ; Douglas *et al.*, 1960 ; Baker and Kelley, 1960 ; Jolles, 1962 ; Bucalossi *et al.*, 1963 ; Stoll, 1965). The trials are summarized in Table I, and from the results it is obvious that there is a place for progestin therapy in breast cancer. To our knowledge no basis has yet been shown for statements that the presence of breast cancer contraindicates the use of progestins because they may possibly stimulate the tumour (Klawans, 1965).

Nevertheless, there still remains the evaluation of the most efficacious agent and the most suitable stage of the disease for its administration. The choice of suitable agent is made more difficult by differences in side-effects, particularly in the incidence of gastrointestinal upset, biochemical evidence of liver damage, and signs of masculinization after prolonged use. For this reason it was thought valuable for one observer, using standardized criteria, to compare examples of each class of progestin in the treatment of advanced breast cancer. This report is of a limited pilot trial of this nature.

Material

A total of 72 postmenopausal women with advanced breast cancer were treated by synthetic oral progestins selected to represent the three major groups in use—that is, 19-nortestosterone derivatives, 17α-hydroxyprogesterone derivatives, and the testosterone derivatives. The initial daily dosage given was in general six times that used in oral contraceptive practice and is noted in Table II. Cases were not randomized, but were allocated on a chronological basis as agents became available for trial.

As well as objective evidence of tumour regression, special note was taken of side-effects from each drug—mainly the immediate ones, but also in a few cases the long-term ones. Special investigations carried out in the majority of patients included liver-function studies and serial cytohormonal assessment of the vaginal smear, both before and during treatment. In some of the later cases glucose-tolerance tests were carried out after at least four weeks of hormone treatment.

All 72 patients had undergone either a natural menopause or castration. They were suffering from advanced breast cancer, beyond the control of both surgery and radiotherapy. All patients had measurable evidence of progressing soft-tissue lesions regularly measured, and photographed when appropriate. Simultaneous treatment of the part under observation was not permitted by any method except local dressings. Patients were selected for drug trial only if the disease was progressing in activity as recorded in serial observations. Previous hormone therapy had been discontinued for at least two months and castration carried out at least six months previously.

Nathanson's (1952) classical criteria of objective response from hormone therapy in breast cancer were used. A response indicates observation of at least 50% regression in size of accessible lesions, while, at the very least, all existing inaccessible lesions remain static in activity and no new lesions appear. Of the 72 patients, there were 65 who received the hormones for two months or longer and were assessed for tumour regression. The patients who discontinued the drugs before completion of two months' treatment are excluded from the analysis as having had insufficient trial. As this was regarded essentially as a screening trial, only patients who showed tumour regression at two months were continued on drug therapy. The earliest macroscopic regression could be identified at four weeks after starting treatment. It was maintained for periods of up to eight months when the drug was continued. Details of response for each patient are shown in Table II, and for each group in Table III.

TABLE III.—*Agents and Dosage Used in this Trial and Clinical Response of Breast Cancer*

Progestin	Daily Oral Dose	Clinical Response in	Group Response	Significance
19-Nortestosterone Derivatives				
Norethisterone acetate	60 mg.	2 of 12	3 of 19 = 16%	Not significant
Lynoestrenol	30 ,,	1 ,, 7		
17α-Hydroxyprogesterone Derivatives				
Medroxyprogesterone ..	200–400 mg.	2 of 12	5 of 28 = 18%	
Melengestrol	120 mg.	1 ,, 5		
Megestrol	30 ,,	2 ,, 11		
Testosterone Derivative				
Dimethisterone ..	300 mg.	4 of 18	= 22%	

Results

Objective response as defined above was noted in 12 of the 65 patients. It was seen in 3 out of 19 cases on the 19-nortestosterone derivatives, in 5 out of 28 on the 17α-hydroxyprogesterone derivatives, and in 4 out of 18 on the testosterone derivative. In the last group there were 8 additional cases where the observed lesions showed regression but less than 50% reduction in size. There is no statistically significant difference in tumour response rate between the groups (Table III). However, the selected example of the testosterone derivatives (dimethisterone) differs in one respect from the other groups in that it yields a high proportion of patients with partial response, similar to that seen from corticosteroid administration (Stoll, 1963). The dose level selected for dimethisterone appears to be near its minimum effective level, as shown in four of these patients where the dosage was halved when the disease appeared to be partially under control. In two of these patients with nodular infiltration of the chest wall the symptoms of itching and tightness, which had eased at full dosage, reappeared at half dosage, but eased again when full dosage was reinstituted.

Of the 65 patients assessed for tumour response on progestins, 40 had undergone a previous trial of oestrogen or androgen therapy (Table IV). When comparing patients previously responding with those not responding to oestrogen or androgen therapy there is no statistical difference in the proportion of progestin responders (Table IV). Of eight progestin responders who had received a previous trial of oestrogens or androgens, only two had responded to these agents. It has also been reported (Stoll, 1966) that 3 out of 10 patients failing to show tumour regression on 15 mg. of stilboestrol daily did show such a regression when progestins were added. It appears, therefore, that there is no obvious correlation between tumour response to progestins and response to previous sex hormone therapy. It seems likely that progestin responders do not belong to the same group of patients as those who respond to the conventional sex hormones.

TABLE IV.—*Response to Progestins in Relation to Previous Hormonal Response*

Previous Hormone Response	Subsequently Responding to Progestins	Significance
Response to oestrogens or androgens ..	2 of 9 (22%)	Not significant
No response to oestrogens or androgens ..	7 of 31 (22%)	

Side-effects

In the total series of 72 cases, side-effects necessitated stopping therapy in seven cases, found only in the first two groups. Severe nausea and vomiting or abdominal pain accounted for five cases; in one case the complaint was of severe mental depression and in another of irritability. Minor side-effects overcome with persistence included nausea, constipation, and backache. Breakthrough bleeding was noted in only three cases in the total series on high doses of progestins.

Unusual side-effects were noted with the selected example of the testosterone derivatives (dimethisterone). Gross increase in appetite, generally associated with a gain in weight, was mentioned by 7 of the 18 patients. In addition, four of the patients in the group noted an improvement in mood in the form of tranquillization. In two cases in this group taking the hormone for longer than five months it caused long-term side-effects in the form of puffiness of the face and hypertrichosis of the face and chin. Segaloff (personal communication, 1965) noted a Cushingoid effect from prolonged therapy with a 17α-hydroxyprogesterone derivative.

Biochemical and histological evidence of liver damage after the administration of oral progestins and oral contraceptives has been reported (Eisalo *et al.*, 1964; Stoll *et al.*, 1966). Total serum bilirubin and serum aspartate aminotransferase levels were assessed fortnightly in 45 cases in the present series. Only in the 19-nortestosterone group were abnormal changes seen in the aminotransferase levels, the first rise appearing after two weeks' drug administration. Liver biopsy carried out in one of the cases showed evidence of parenchymal cell necrosis with accumulation of lipofuscin (Stoll *et al.*, 1966). In the present series there were no cases with clinical signs of jaundice or a raised bilirubin level.

Glucose-tolerance tests were carried out in eight cases after at least four weeks' drug administration. Abnormally high blood glucose levels after one hour were noted in one of the eight cases (compared with three of four cases in a similar therapeutic trial of Lyndiol (Stoll 1967a)). The liver-function tests showed no gross abnormality in the patients with abnormal blood glucose levels.

Pretreatment Vaginal Smear

The adrenal cortex secretes androgens throughout life in the female. In addition, the secretion of oestrogens and progesterone does not cease with atrophy of the ovary at the menopause, as breakdown products of both these corticosteroids have been shown in the urine in postmenopausal women (Klopper *et al.*, 1955; Nissen-Meyer and Sanner, 1963). The major part of these corticosteroids originates in the adrenal cortex and their circulating levels are reflected in the vaginal smear. It should be noted that the distribution of vaginal smear patterns in postmenopausal patients suffering from breast cancer is no different from that of a control group of normal postmenopausal women of the same age group (Struthers, 1956; Finkbeiner, 1960).

Cytohormonal assessment of the vaginal smear was carried out before initiating treatment in all but one of the patients. After the menopause two main smear patterns are observed, an atrophic pattern and an intermediate pattern. The former indicates a complete absence of sex-hormone stimulation. The latter pattern reflects a response to adrenal hormones, but cytologists disagree on whether it reflects oestrogenic or androgenic substances or a mixture of the two.

The pretreatment vaginal smears were classified by the cytologist as atrophic if over 80% of the cells were parabasal in type, and intermediate if over 80% of cells were of the intermediate type. It is shown in Table V that whereas only 5% of patients with an atrophic smear responded to progestin therapy, 29% of patients with an intermediate smear responded. The difference is statistically significant ($P<0.03$). The pretreatment smear can therefore be used to select patients for progestin therapy in the same way that the "discriminant factor" is used before adrenalectomy or hypophysectomy in advanced breast cancer (Atkins, 1966). It is interesting that in our experience the pre-treatment vaginal smear cannot be correlated with the likelihood of a response either to oestrogens or to androgens (Stoll, 1967b).

TABLE V.—*Clinical Response to Progestins (Described in This Paper) in Relation to Initial Vaginal Smear. Parallel Figures for Lyndiol (Stoll, 1967a) for Comparison*

Hormone Therapy	Proportion of Cases Responding if Initial Vaginal Smear		Significance
	Intermediate	Atrophic	
Progestins ..	11 of 38 (29%)	1 of 21 (5%)	$P<0.03$
Lyndiol ..	8 „ 20 (40%)	1 „ 16 (6%)	$P<0.03$

Effect of Progestins on the Vaginal Smear

The 19-nortestosterone derivatives used in this trial are norethisterone acetate (17α-ethynyl derivative) and lynoestrenol (17α-ethynyl-3-deoxy derivative). Some members of this group show oestrogenic properties and, in addition, the group tends to be androgenic in experimental animals.

The 17α-hydroxyprogesterone derivatives used in this trial are medroxyprogesterone (6-methyl derivative), megestrol (6-dehydro-6-methyl derivative), and melengestrol (16-methylene derivative of megestrol). The testosterone derivative used was dimethisterone (6α,21-dimethylethisterone). These latter two groups of compounds are said to possess no inherent oestrogenicity and no significant androgenic activity in the experimental animal (Goldzieher, 1964).

Serial vaginal smear tests were carried out at two-weekly intervals during progestin therapy in 42 cases. In 16 of these patients who showed a pre-treatment atrophic pattern there was a change to the intermediate pattern in only three after the administration of progestins. One case was recorded in each of the groups—that is, the 19-nortestosterone derivatives, the 17α-hydroxyprogesterone derivatives, and the testosterone derivatives. This picture presumably reflects some degree of inherent oestrogenicity or androgenicity in the compounds involved (Table II).

Discussion

By definition, a progestational agent is one which causes a secretory response in the uterine lining after oestrogen priming. The many synthetic orally active progestational agents available have marked qualitative differences in their oestrogenicity, androgenicity, and metabolic activity. We prefer to use the term "progestins" rather than "progestogens" or "progestational agents," because their major clinical use in recent years has not been for assistance in the initiation of pregnancy. The mode of action of progestins in breast cancer may be by:

1. *Effect on Anterior Pituitary Secretion.*—There is conflicting evidence concerning the effect of progestins on total gonadotrophin excretion (Brown *et al.*, 1964). Nevertheless, it is possible that a decrease in the luteotrophin secretion alone may be the effect common to these agents (Diczfalusy, 1965). They are also said to stimulate release of mammotropin from the pituitary (Kim, 1965).

2. *Conversion of Progestins to Another Active Steroid—such as Androgen or Oestrogen.*—It is believed that some of the 19-nortestosterone derivatives have both androgenic and oestrogenic metabolites. Our vaginal smear observations suggest that this may be true of some members of the other groups also.

3. *Local Effect on the Breast Tumour.*—The possibility of a local effect by progestins on the tumour is shown by Kim's (1965) observation that in the hypophysectomized animal there is a growth-promoting effect on hormone-sensitive mammary cancer by the combined administration of oestradiol and progesterone, but not from oestrogens alone.

Recent experimental reports suggest a fourth possible mode of action. Huggins *et al.* (1962) reported a hormone-sensitive chemically induced mammary cancer in female rats. They reported that oestradiol 20 μg. daily will depress tumour growth, but its combination with 4 mg. of progesterone daily will actually ***extinguish*** tumour growth in the majority. Young *et al.* (1963) noted that the administration of oestradiol after oophorectomy causes tumour reactivation in less than 50% of such rats, but the addition of progesterone causes reactivation in 95% of cases. Similarly, though Sterental ***et al.*** (1963) showed no reactivation of the experimental cancer by oestrogen administration after hypophysectomy, Kim (1965) noted that the combination of oestradiol and progesterone has a very potent growth-promoting effect in the hypophysectomized animal.

All these observations can be interpreted as suggesting a fourth possible mode of action of progestins in breast cancer. It is possible that progesterone acts by sensitizing experimental mammary cancer in rats to the action of oestrogens, whether in the form of stimulation or of depression of tumour growth. If this applies to man one would not expect to obtain significant response of breast cancer to progestin therapy in the absence of oestrogens. This may account for the very poor response rate seen in patients with an atrophic vaginal smear, as such a smear indicates a complete absence of oestrogen stimulation in the postmenopausal woman.

A previous paper (Stoll, 1967a) reported the effect on advanced breast cancer of Lyndiol, a commercially available oral contraceptive containing lynoestrenol, a progestin of the 19-norsteroid group, combined with the oestrogen mestranol. The proportion of responders was similar to that noted in this paper for progestin-treated cases (Table V). The addition of oestrogen (in the form and dose found in Lyndiol) does not seem to increase the response rate in the patient with an atrophic vaginal smear.

There may be some selectivity of action by particular progestins. There were five patients to whom dimethisterone was given after failure of previous progestins, and in two of them tumour response (by full criteria) was noted. However, dimethisterone given to five patients after failure of Lyndiol gave no response. It is suggested that the metabolism of different progestins might be investigated in breast cancer patients by the administration of radioactively tagged progestins. This would establish whether there is indeed a direct effect on the target organ cells. In addition, the distribution of the radioactive hormone in the tumour could be estimated by autoradiography, since localization is probably not uniform and depends on vascularity, patchy necrotic changes, or other factors.

Summary

The effect of representatives of the three major groups of progestins is compared on metastatic soft-tissue growth of breast cancer in postmenopausal women.

Objective regression of soft-tissue tumour was noted in 12 out of 65 patients treated for two months or longer. Differences in side-effects and liver toxicity between the groups are noted. In addition, a corticosteroid-like effect of one agent on breast cancer is noted.

It is possible to differentiate patients with a 29% likelihood of response from those with only a 5% likelihood of response by cytohormonal examination of the postmenopausal vaginal smear before therapy.

The possible mode of action of progestins in breast cancer is discussed.

My thanks are due to Dr. W. J. Moon for many stimulating discussions in the course of this project.

Heart Block and Coronary Artery Disease

M. J. DAVIES,* M.B., B.S.; D. REDWOOD,† M.A., M.B., B.CHIR., M.R.C.P.; A. HARRIS,† M.B., B.S., M.R.C.P.

Brit. med. J., 1967, 3, 342–343

Acute heart block is an uncommon but serious complication of myocardial infarction, though survivors usually return to sinus rhythm.

Chronic heart block associated with Stokes–Adams attacks is also often assumed to be ischaemic in origin. Some clinical reviews have, however, stressed the high incidence of "primary" heart block (Zoob and Smith, 1963; Johansson, 1966). Initial studies from this hospital suggested that significant coronary artery disease was not present in most cases of chronic heart block and that pathological changes were often confined to the conduction system (Portal *et al.*, 1962).

A detailed post-mortem study of both acute and chronic heart block has now been carried out to define the part played by coronary disease in the production of complete heart block.

Material and Methods

The material comprised the hearts from 14 cases of atrioventricular (A-V) block associated with acute myocardial infarction and 53 cases of chronic complete heart block. Many of the hearts from cases of acute infarction were received as post-mortem specimens from other hospitals. The majority of cases of chronic heart block had Stokes–Adams attacks and had been referred to this hospital for pacing. The average age at death for this group was 62. A control series of 35 hearts obtained from routine necropsy material was studied in an identical manner. The control subjects were over the age of 50 at the time of death and had had a normal electrocardiogram in the last three months of life.

Post-mortem examination of the hearts included coronary angiography (Crawford *et al.*, 1961) and serial sections of the coronary arteries at 5-mm. intervals. The degree of atherosclerosis in the coronary arteries was assessed by scoring the degree of stenosis in each of 16 segments, after the method of Eusterman *et al.* (1962). The entire conduction system was studied by use of a serial histological section technique (Davies, 1967).

Results

Acute Infarction.—In 9 of the 14 cases of acute infarction there was thrombotic occlusion of a dominant right coronary artery which supplied the posterior wall of the heart and ultimately the A-V node. In four cases there was occlusion of a dominant left circumflex artery supplying the posterior wall of the heart and A-V node. These 13 cases showed recent posteroseptal infarction. In the remaining patient there was occlusion of the anterior descending coronary artery with a large anteroseptal infarct involving both bundle branches. The site of damage to the conduction system in acute infarction is shown in Table I. Pathological changes in the conduction system with the usual posteroseptal infarct were often relatively minor. If major damage occurred the changes were found in the bundle branches.

2. *Chronic Heart Block.*—The lesions in the conduction system responsible for chronic heart block in 53 cases are shown in Table II. Coronary disease was the cause in only eight and was associated with destruction of both bundle branches in the scarring of old septal infarction. In five of the eight cases this was posteroseptal and in three anteroseptal. Severe atherosclerosis was present in all cases, and recanalized or old occlusions were demonstrable in the coronary arteries in relation to the areas of old infarction. The commonest cause of chronic complete heart block was bundle-branch fibrosis, which accounted for 21 cases. Loss of conduction fibres had occurred in the upper two-thirds of both bundle branches. The immediately adjacent myocardium was normal. The coronary arteries in this group showed no significant degree of atheroma and did not differ from the control group when scored for coronary artery disease, the method devised by Eusterman *et al.* (1962), with serial (5-mm.) sections of the coronary arteries, being used. Focal myocardial scarring was increased compared with the controls, but major pathological changes were more or less confined to the conduction system.

TABLE I.—*Pathology of the Conduction System in 14 Cases of Acute Infarction and Complete Block*

Lesions		No.	Site of Infarction
Normal conduction system		4	Posteroseptal
Focal necrosis in A-V node	Minor pathological changes	3	,,
Partial necrosis of left branch		4	,,
Total necrosis of left branch		1	,,
Complete necrosis of both branches		2	One posteroseptal, one anteroseptal

TABLE II.—*Aetiology of 53 Cases of Chronic A-V Block at Necropsy*

Bilateral bundle branch fibrosis	21 (40%)
Coronary artery disease	8 (15%)
Cardiomyopathy	8
Calcification of valve rings	4
Active myocarditis	2
Rheumatic myocarditis	2
Collagen disease	3
Congenital lesion	1
Aneurysm of membranous septum	1
Amyloidosis	2
Transfusion siderosis	1

Discussion

This paper is concerned only with the relation of coronary artery disease to complete heart block. Detailed analysis of other and more common causes of heart block are reported elsewhere (Davies, 1967).

In the majority of patients who develop complete heart block as a complication of myocardial infarction the conduction disturbance is transitory. This feature has been stressed in clinical reviews, and few survivors need long-term pacing (Penton *et al.*, 1956; Gilchrist, 1958; Harris and Bluestone, 1966). Even in those who die major structural damage to the conduction system is found in only a minority. In most cases it is therefore reasonable to presume that heart block is due to anoxia of the A-V node secondary to an occlusion of the dominant coronary artery, usually the right, which supplies the node. In a minority with acute infarction major damage is found to involve the bundle branches, and only if both branches are totally destroyed will block be permanent.

In the eight cases of chronic heart block due to coronary artery disease, comprising only 15% of those with chronic A-V block, there was destruction of both bundle branches in

† Department of Cardiology, St. George's Hospital Medical School, London S.W.1.

areas of old infarction. This figure is in close agreement with that of Johansson (1966), who, on clinical criteria, suspected that only 24 out of 142 cases (17%) of chronic heart block were ischaemic in origin. He offered no pathological explanation for 64 out of 142 cases (45%) which were classified as "primary" heart block. In the present post-mortem series 21 out of 53 cases (40%) were due to bundle branch fibrosis. The pathological basis of primary heart block is therefore bilateral bundle-branch fibrosis; the cause remains unknown, but it is certainly not due to coronary artery disease.

Summary

In a post-mortem study of 53 hearts from patients with chronic atrioventricular block only 8 (15%) were due to coronary artery disease. Bundle-branch fibrosis of unknown aetiology, without major damage to the contractile myocardium, is the commonest cause, being present in 21 cases (40%).

In 14 cases of acute myocardial infarction and A-V block major structural damage to the conduction system was unusual, but, when present, involved the bundle branches.

This work was done during tenure of the William Shepherd Research Fellowship from the Board of Governors of St. George's Hospital. We would like to thank Dr. A. Leatham and Dr. W. B. Robertson for their help in preparing this paper.

Dip-Slide: An Aid to Quantitative Urine Culture in General Practice

DENNIS GUTTMANN,* M.A., M.B., B.CH., B.SC., M.R.C.P.; G. R. E. NAYLOR,† M.A., M.D., M.R.C.P., M.C.PATH.

Brit. med. J., 1967, **3**, 343–345

Since Kass (1956) defined criteria of significant bacteriuria, the use of quantitative assessments of the bacterial population as an aid to the differentiation between infection and contamination of the urine has gained wide acceptance. The pour-plate method is recognized as the standard technique for performing viable counts on urine, but requires trained staff for setting up the cultures. If misleading results are to be avoided, urine specimens must be cultured within an hour or two of collection, or be refrigerated; in general practice it is often difficult to fulfil these requirements. Further, the examination of large numbers of specimens, as at antenatal clinics and in population surveys, makes demands on laboratory services which may become prohibitive if the pour-plate method is employed routinely. A number of simpler cultural methods have been described, such as the filter-paper strip inoculation technique of Leigh and Williams (1964), and the semiquantitative methods of Cattell and Lefford (1963) and of Guttmann and Stokes (1963). Though these are technically less complicated, they are still dependent on the delivery to the laboratory of freshly passed specimens.

Mackey and Sandys (1965, 1966) described a dip-inoculum transport medium in which a metal or plastic spoon carries the culture medium, and which may be inoculated by simply dipping in the specimen, after which it need not reach the laboratory for incubation for 24 or 48 hours. Using standard materials readily available in most laboratories, we have investigated a similar method which we feel has a number of advantages. An ordinary 3- by 1-in. (7.5- by 2.5-cm.) glass microscope slide is coated for a length of about 2 in. (5 cm.) with nutrient agar on one side and with MacConkey's agar on the other. It is held in a small cylindrical aluminium container as supplied in the Public Health Laboratory Service for the collection of faeces specimens. This dip-slide is inoculated by dipping the coated end into the fresh urine specimen. After allowing excess urine to drain for a few seconds, the slide is returned to its container and after replacing the screw cap it is sent to the laboratory, if necessary by post. After overnight incubation the number of colonies which have grown on the slide is counted with a hand lens. The preparation is cheap enough to be discarded after use, and an extensive trial has shown the method to give clinically valuable results. Fig. 1 shows the dip-slide and its aluminium container. Full details of the preparation of the dip-slides are given elsewhere (Naylor and Guttmann, 1967).

Dilutions of broth cultures of Gram-negative rods and Gram-positive cocci isolated from pyogenic infections of the urinary tract were examined by dip-slide inoculation and simultaneous viable bacterial counts: we found a straight-line relationship between the number of colonies on the dip-slide and the number of organisms in the fluid into which it had been dipped; 50 to 100 colonies on the dip-slide correspond to a viable bacterial count of 10,000 per ml. (Naylor and Guttmann, 1967). Fig. 2 shows a series of dip-slides prepared from dilutions of a culture of *Escherichia coli*, and it will be seen that separate colonies readily countable with a hand lens were obtained up to a concentration of 0.6×10^5 organisms per ml. The results of a clinical trial are reported in more detail below.

Methods

From outpatients attending a urinary infection clinic 385 consecutive mid-stream urine specimens were obtained and examined in parallel by the dip-slide, a pour-plate viable count, and the semiquantitative method of Guttmann and Stokes (1963). The last 100 specimens were inoculated on to dip-slides with cycloheximide added to the nutrient agar at a concentration of 100 μg./ml. of medium, as well as on to ordinary dip-slides. Cycloheximide prevents the growth of air-borne mould spores which occasionally were found to contaminate some of the slides during preparation, thus creating difficulties if the dip-slides were stored for some weeks before use. Such a concentration of cycloheximide did not interfere with the growth of bacteria isolated from urine specimens.

Microscopy of the Gram-stained deposit and tests for protein were performed, and white cell excretion rates were estimated by the method of Houghton and Pears (1957), the patients having been instructed to empty the bladder two to three hours before attending the clinic. Preparation of female patients consisted of washing the vulva and perineum with soap and water and drying with a clean towel. Where possible the vaginal orifice was plugged with cotton-wool. A clean catch mid-stream specimen was obtained for bacteriological examination, which was subsequently combined with the remainder of the voided bladder contents for estimation of white cell excretion rates. All specimens were processed within three hours of collection, those which could not be cultured within one hour being refrigerated meanwhile.

† Public Health Laboratory Service, Cambridge.

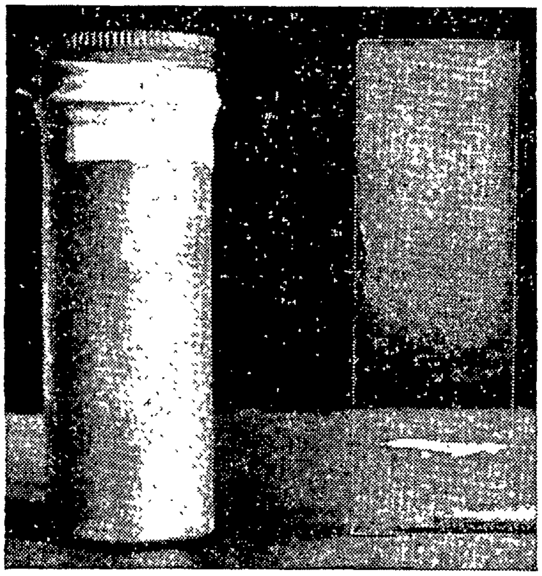

FIG. 1.—The dip-slide.

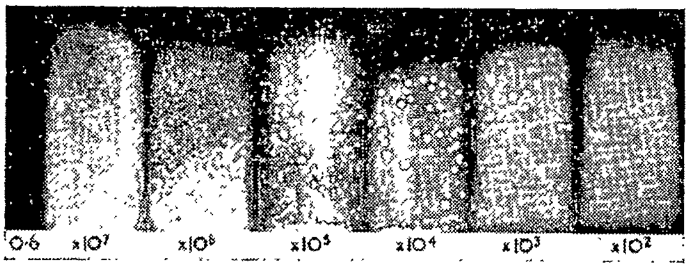

FIG. 2.—Dip-slides inoculated from tenfold serial dilutions of a culture of *E. coli.*

All patients attending the urinary infection clinic had evidence of past or present infection of the urinary tract, and over half the specimens were obtained from patients receiving chemotherapy.

Results

Forty-two specimens were found to contain more than 10^6 organisms per ml., and all these gave a confluent growth on both sides of the dip-slide, except one specimen containing a heavy growth of a coagulase-negative staphylococcus, where no growth was obtained on MacConkey's agar. Fifty-two specimens contained fewer than 100 organisms per ml. and gave no growth on the dip-slide. Culture results on the remaining 291 specimens are shown in Fig. 3; these include 30 specimens containing fewer than 100 organisms per ml., but showing some growth on the dip-slide. The dip-slide colony counts refer to the side of the slide coated with nutrient agar, except where this was overgrown with swarming organisms when the side coated with MacConkey's agar was counted. It will be seen that there is good correlation between the pour-plate counts and the numbers of colonies grown on the dip-slides, the moderate degree of scatter causing no practical difficulty in the interpretation of the results. Essentially similar results were obtained with Gram-negative rods and Gram-positive cocci.

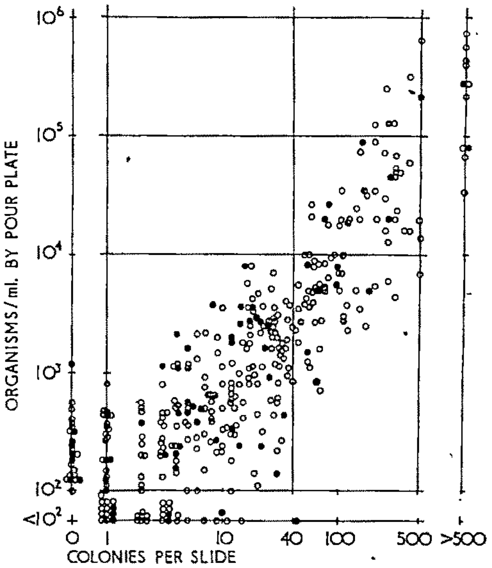

FIG. 3.—Comparison of dip-slide colony counts and viable bacterial counts by the pour-plate method. ○=Ordinary media. ●=Nutrient agar containing cycloheximide 100 μg./ml. (See text.)

In our series of 385 specimens there were 37 which contained between 10^4 and 10^5 organisms per ml., and produced dip-slide counts from 50 to 500 colonies. Six of this group, all from patients receiving chemotherapy, were found by routine methods to give pure cultures of pathogenic organisms, showed protein and increased white cell excretion rates, and were considered to reflect active urinary infection. These could be readily distinguished from heavily contaminated specimens by examination of the dip-slides, the purity or mixed nature of the growth being obvious at this concentration. We believe that there is little danger of missing an active infection of the urine by the dip-slide method even if the viable bacterial count is less than 10^5 organisms per ml. In 4 out of the remaining 31 specimens containing 10^4 to 10^5 organisms per ml. which by routine methods were considered to be heavily contaminated, the dip-slide was wrongly interpreted as indicating true infection; the incidence of false-positive results is therefore acceptably small when the whole series of 385 specimens is considered.

Dip-slide in General Practice

Dip-slides have been used by a number of general practitioners in the Cambridge area, the inoculated slides being sent to the Public Health Laboratory for incubation and reporting. No practical difficulties were experienced and the culture results have been clinically helpful. They have been particularly useful when urine specimens have had to be sent by post, and also when patients attended evening surgeries held after normal laboratory working hours.

A number of patients attending the urinary infection clinic were asked to inoculate dip-slides at home. They were instructed to dip the slide into a mid-stream specimen passed, after perineal toilet, into a basin rinsed with boiling water and allowed to cool, or to wet both sides of the dip-slide in the urine stream while holding the uncoated end in a clothes peg. Preliminary tests showed that the media adhere to the slide firmly enough not to be washed off when the preparation is inoculated in this way. The dip-slide could also be inoculated by pouring urine over both sides if the specimen was collected in a vessel unsuitable for dipping. No difficulty was experienced with excessive contamination of dip-slides inoculated by patients themselves. Home inoculation was found to be of particular value in patients who developed urinary symptoms between visits to the clinic and were unable to attend for a specimen to be collected and examined by routine methods. The response of established infections to chemotherapy could also be followed on an outpatient basis, slides being inoculated on several consecutive days after starting treatment.

Discussion

The dip-slide is based on Mackey and Sandys's idea of a dip-inoculum transport medium. It is made from easily available materials and is cheap. It has two further advantages. Firstly, two media are inoculated simultaneously. This helps considerably in distinguishing between pure cultures of pathogenic organisms and mixed growths due to contamination. Secondly, a larger surface area of medium is available for inoculation. This makes colony counting easier, and the transparency of the preparation is also helpful in this respect. Up to 500 colonies can be easily separated on one side of the dip-slide, the growth becoming confluent only with counts approaching 1,000 colonies. Our clinical trial shows that all specimens containing more than 10^5 organisms per ml. gave dip-slide counts of 200 or more colonies, and specimens with more than 10^4 organisms per ml. produced counts above 40 colonies. Colony counts between 40 and 200 are particularly convenient to read.

We suggest that dip-slide colony counts between 100 and 500 should be regarded as doubtful and an indication for further investigation of the patient. In our series there were 45 specimens in this range, of which eight were considered to be truly infected. It must be remembered that our patients were highly selected, and it is probable that in a random population the incidence of doubtful results would be smaller.

The dip-slide has been in clinical use for over one year. In general practice it was found to overcome difficulties in bacteriological diagnosis which may arise when there is an unavoidable delay between collection of the specimen and its delivery to the laboratory. The ease of inoculation makes it useful in screening clinics where large numbers of specimens have to be processed. With a little experience the majority of dip-slides may be assigned to significantly or non-significantly infected groups by inspection without counting colonies. The quantitative accuracy of the method is greater than that obtained by standard-size loop inoculation methods ; on the other hand, the identification of bacterial species and subculturing are easier than from a pour plate. In our series, which included 60 specimens shown to be infected by conventional methods, the dip-slide yielded no false-negative results, and false-positive results were also not a problem.

We regard the dip-slide as an adjunct to conventional methods of urine examination. It does not obviate the need for microscopy of the deposit, tests for protein, or cultures for the identification of the infecting organism. We do not suggest its introduction for routine use where specimens can be delivered to the laboratory quickly after collection. It may, however, be conveniently used as the only screening method in surveys such as at antenatal clinics. Patients from whom specimens are obtained with dip-slide colony counts in the infected or doubtful range would then be recalled for further investigation by routine methods.

Summary

A dip-inoculum transport medium for the diagnosis of significant bacteriuria is described, consisting of a microscope slide coated with culture media. Laboratory and clinical testing shows the dip-slide to give consistent quantitative results which compare well with pour-plate viable counting.

The dip-slide enables ready differentiation between heavy contamination of urine specimens and genuine infection. In a series of 385 specimens no false-negative results were obtained, and there was an insignificant number of false-positive cultures.

The dip-slide is recommended whenever there is likely to be delay in delivery of urine specimens to the laboratory. It is particularly useful in general practice if specimens have to be sent by post. Owing to the ease of inoculation and reading it is also suited to the routine screening of large numbers of specimens such as at antenatal clinics.

We wish to thank Miss I. J. Barker, Miss V. A. Lane, and Miss S. E. Minns for technical assistance, and the outpatient nursing staff of Addenbrooke's Hospital for their skill in obtaining satisfactory urine specimens. One of us (D. G.) is grateful to Dr. M. H. Gleeson-White for provision of laboratory facilities.

Sodium Uptake in Peritoneal Dialysis

J. D. SWALES,* M.B., M.R.C.P.

Brit. med. J., 1967, **3**, 345–347

Peritoneal dialysis has come to occupy a prominent place in the treatment of renal disease, and has, indeed, largely replaced haemodialysis in some centres (Cameron, 1966). Pulmonary complications frequently occur, though in many cases they consist of asymptomatic segmental collapse (Berlyne *et al.*, 1966). An occasional, and more often fatal, complication is acute heart failure. In a recent series of 91 patients this complication accounted for two deaths (Stewart *et al.*, 1966).

When dialysis fluid cannot be drained from the peritoneal cavity, fluid overload and heart failure are easily accounted for in terms of the slow absorption of dialysis fluid. However, even where the patient is not in positive fluid balance, heart failure may occur during the course of peritoneal dialysis (see Case Report below). The purpose of this paper is to present data on sodium absorption during 13 consecutive peritoneal dialyses, to suggest that it is the uptake of sodium in hyponatraemic patients which is responsible for the development of heart failure, and to suggest how this potentially fatal complication may be avoided.

Case Report

A 14-year-old schoolboy gave a history of lifelong nocturia. For five years he had had polydipsia and polyuria with recurrent dysuria. In March 1965 he was found to have a blood urea of 450 mg./

---

* Registrar, Medical Professorial Unit, Westminster Hospital, London S.W.1

100 ml., and serum sodium 123, potassium 6.5, and bicarbonate 12 mEq/l. Treatment by continuous bladder drainage and sodium supplements produced a marked improvement and his urea fell to 70 mg./100 ml. He continued as an outpatient, taking 2 g. of sodium chloride and 2 g. of sodium bicarbonate daily. Six months later he was readmitted with a week's history of vomiting. Apart from slight drowsiness there were no abnormal physical signs. His blood pressure was 110/70 mm. Hg. The blood urea was 404 mg./100 ml., serum sodium 125 mEq/l., and serum potassium 4.6 mEq/l. His sodium supplements were stopped, and peritoneal dialysis was started. The dialysis was technically satisfactory in that after eight exchanges he was in a negative fluid balance of 400 ml. However, after 12 hours he became slightly hypertensive (135/95 mm. Hg) and developed an apical gallop rhythm (III sound). At the beginning of the ninth exchange, 22 hours after starting dialysis, he suddenly became acutely dyspnoeic and cyanosed, with fine crepitations over both lung fields. He showed no response to aminophylline, digoxin, and oxygen therapy, and died 20 minutes later. Post-mortem examination showed severe pulmonary oedema with bilaterally shrunken pyelonephritic kidneys containing numerous small cysts.

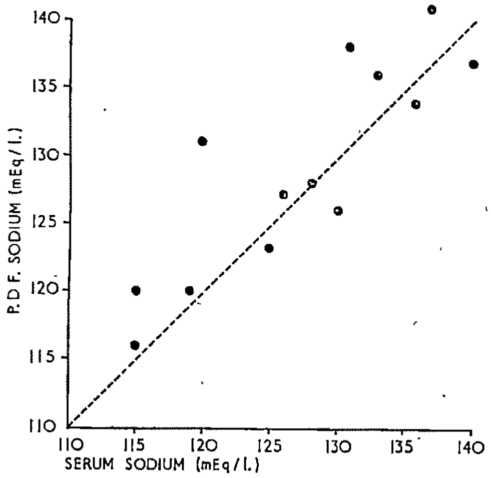

FIG. 1.—Sodium concentration simultaneously measured in serum and peritoneal dialysis fluid at start of peritoneal dialysis.

Comment.—This patient developed a dramatic and fatal pulmonary oedema, though fluid had actually been withdrawn. It could be postulated that significant amounts of sodium were moving along the concentration gradient between the peritoneal dialysis fluid (141 mEq/l.) and his serum (125 mEq/l.), and that this caused the acute pulmonary oedema. No quantitative study has hitherto been made of sodium movements during peritoneal dialysis in relation to the serum sodium concentration. In order to ascertain whether such an uptake of sodium occurs the following study was carried out.

Method

Peritoneal dialysis at this hospital is performed by running in a solution of dextrose (1.36 or 6.36 g./100 ml.) containing the following ions: sodium 141, calcium 3.6, magnesium 1.5, chloride 100.8, bicarbonate (as lactate) 44.6 mEq/l. Generally two such disposable plastic bags are used (Allen and Hanburys). The fluid is warmed to 37° C. and run into the peritoneal cavity through a subumbilical catheter as quickly as possible—usually about 10 minutes. After 45 minutes the fluid is drained out through the same catheter and along a side arm attached to the giving set, which leads to a Winchester bottle beneath the patient's bed. A pressure of −5 mm. of mercury is applied to this bottle by means of a Roberts pump. As much fluid as possible is removed, and then two more bags of fluid are run in. The dialysis in this series continued for 18 to 72 hours. During this period 20 to 35 exchanges were possible.

For this study 13 consecutive dialyses on seven uraemic patients were observed. All the patients were either anuric or severely oliguric and remained so during the period of study. A record was obtained of the type and volume of fluid drained. An aliquot was taken from the dialysis fluid returned from each exchange, and the sodium concentration estimated by means of a flame photometer. Daily serum sodium measurements were also made on the patients.

Results

The serum sodium concentration was low initially in most patients, but generally rose during peritoneal dialysis. The sodium concentration of the peritoneal dialysis fluid which drained from the patient was proportional to the serum sodium concentration, though the dialysis fluid sodium tended to be higher (Fig. 1). This suggests incomplete equilibration between the two fluids.

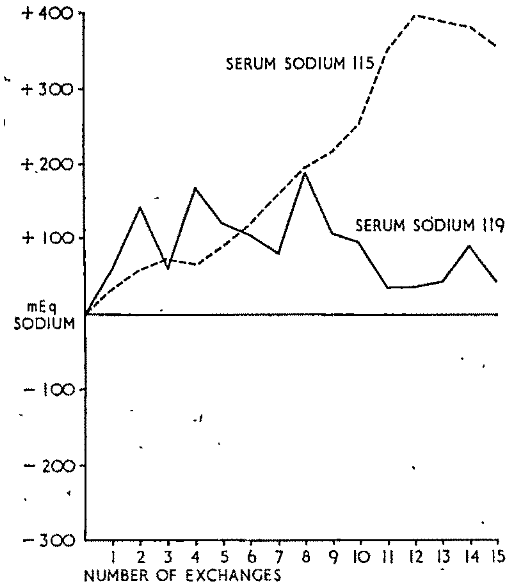

FIG. 2

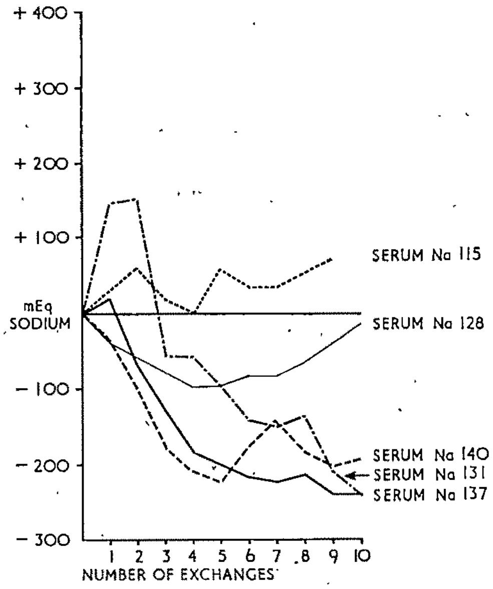

FIG. 3

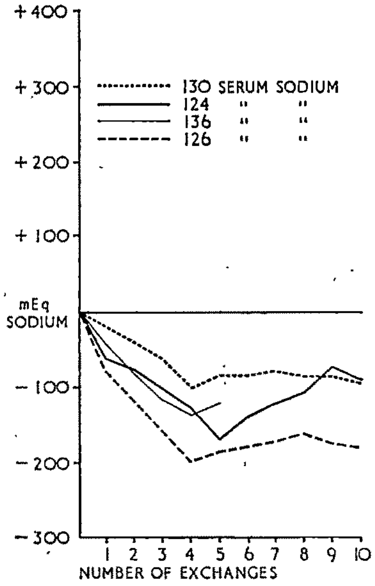

FIG. 4

FIG. 2.—Sodium balance in two patients from whom only small amounts of fluid were removed (0–150 ml. per exchange). FIG. 3.—Sodium balance in five patients from whom 150–300 ml. per exchange was removed. FIG. 4.—Sodium balance in four patients from whom large amounts of fluid were removed (300–450 ml. per exchange).

Four patients developed a positive sodium balance during peritoneal dialysis. In one patient this had reverted to a negative balance by the end of the dialysis. The nature of the sodium balance depended partly on the amount of fluid which was removed (Figs. 2–4) and partly on the initial serum sodium level. Where only a small amount of fluid was removed from a patient with a low serum sodium, a positive sodium balance developed. Two patients are omitted from Figs. 2–4. In one a positive fluid balance occurred because of inadequate drainage, and this was responsible for the sodium uptake of 453 mEq, and in the other fluid was removed more rapidly than in the rest of the series (450 ml. per exchange), with a rapidly developing negative sodium balance in excess of 400 mEq.

Discussion

Urea and electrolytes diffuse along the concentration gradient between fluid within the peritoneal cavity and the serum (Boen, 1961). This process continues until equilibrium is reached after 90 to 120 minutes. During this period the difference in osmolalities determines the volume of fluid absorbed (Shear *et al.*, 1965). The latter workers have shown that subsequently a phase of isotonic absorption occurs when 29.7–39.3 ml. of fluid is absorbed per hour. This latter phase is usually unimportant in peritoneal dialysis, where fluid is not allowed to remain in the peritoneal cavity longer than 45 minutes.

The present study was undertaken to quantify the sodium transfer during the initial period of equilibrium and to determine whether such movement would be physiologically important. The results suggest that significant amounts of sodium are absorbed when a hyponatraemic patient undergoes peritoneal dialysis in which only small amounts of fluid are removed. This may account for the occasional episode of pulmonary oedema during peritoneal dialysis which, as in the case described, may be fatal.

How can this complication be avoided? One answer would be to lower the sodium concentration of the fluid administered. This would necessitate the preparation of several types of dialysis fluid, containing different concentrations of sodium, making the management of peritoneal dialysis a much more complicated operation. Alternatively, one could reproduce the situation seen in the majority of cases in this series, and withdraw large volumes of fluid from the patient by means of the dialysis. The present series shows that this keeps the patient in negative sodium balance.

Hypertonic dialysis fluid may remove greater quantities of urea than isotonic fluid. This is not merely due to the increased amount of fluid withdrawn, but is also partly attributable to the phenomenon known as "solvent drag." When a large volume of fluid passes through a porous membrane, solute tends to move with it, even against a concentration gradient. It has been postulated that solute particles (in this case urea) are entrained in the solvent stream (Henderson, 1966). In order to determine whether sodium could be withdrawn in such a way by using a hypertonic fluid, peritoneal dialysis fluid containing 6.36 g. of glucose per 100 ml. was administered intermittently and the sodium concentration after each such exchange measured. This failed to produce any increase in the sodium concentration of the dialysis fluid removed (see Table).

Effect of Varying Glucose Concentration on Sodium Concentration of Fluid Drained from a Peritoneal Dialysis

Dialysis fluid glucose (g./100 ml.) ..	1·36	1·36	6·36	6·36	1·35
Sodium concentration of effluent (mEq/l.)	125	126	123	122	125

Nevertheless, the present series of cases indicates that if a patient on peritoneal dialysis is kept in a negative fluid balance of several litres there is little danger of excessive sodium absorption.

Summary

In hyponatraemic patients there is a marked gradient between concentration of sodium in the peritoneal dialysis fluid and the serum. In order to establish whether this causes a positive sodium balance the sodium uptake was measured during dialysis. In 4 out of 13 dialyses there was a positive sodium balance, in one case reaching 400 mEq, despite a negative fluid balance in three of these cases. It is suggested that this may be responsible for acute heart failure during dialysis.

Thalassaemia and Hydrops Foetalis—Family Studies

DAVID TODD,* M.D., F.R.C.P.ED.; MICHAEL LAI,† B.SC.; CAROLINA A. BRAGA,‡ M.A., M.B., B.S., M.R.C.O.G.

Brit. med. J., 1967, **3**, 347–349

Stillbirth or neonatal death associated with severe hydrops foetalis, hypochromic anaemia, erythroblastosis, and large amounts of haemoglobin Bart's was first described by Lie-Injo and Jo (1960). In subsequent studies Lie-Injo (1962) and Lie-Injo, Lie, Ager, and Lehmann (1962) reported that the parents of such infants showed haematological changes consistent with α-thalassaemia trait, and they thought that the hydropic babies were homozygous for α-thalassaemia. Reports by Diamond, Cotgrove, and Parker (1965) and Pootrakul, Wasi, and Na-Nakorn (1966) lend support to this view.

In Hong Kong haematological studies have been made on the families of seven Chinese babies with severe hydrops foetalis associated with over 75% of haemoglobin Bart's, and, while there was evidence that five were homozygous for α-thalassaemia, in two a possible interaction between α- and β-thalassaemia was suggested. The purpose of this communication is to report these studies.

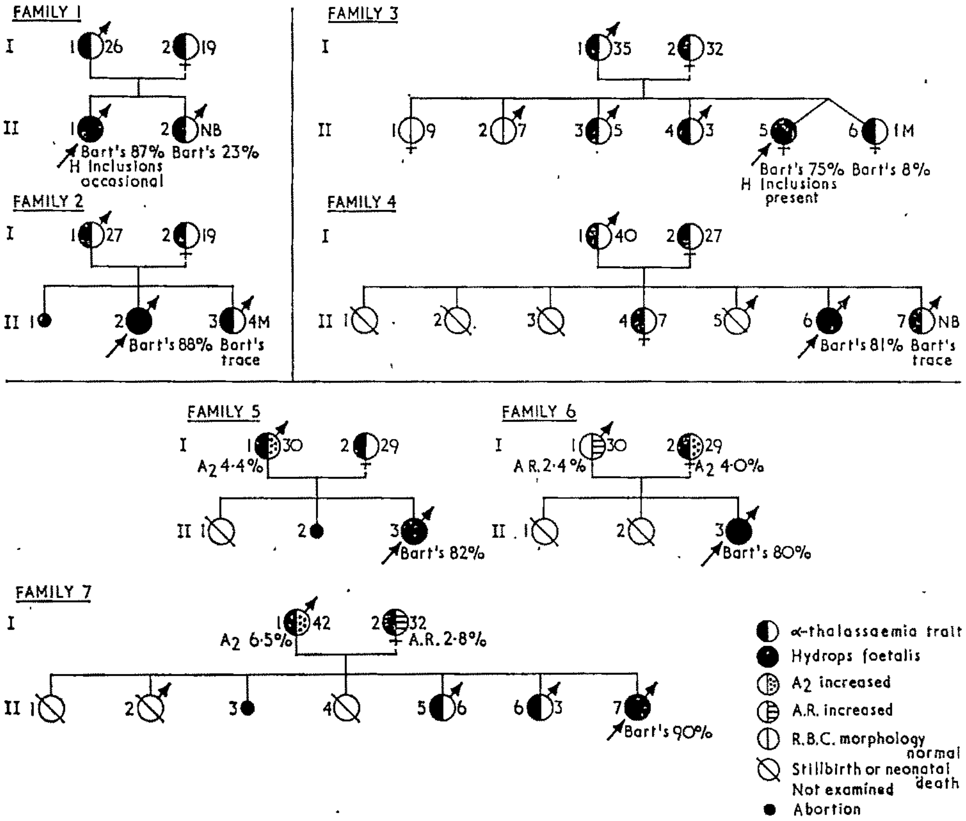
‡ Senior Lecturer, Department of Obstetrics and Gynaecology, University of Hong Kong

Material and Methods

All the subjects studied were Chinese and comprised seven stillborn babies with severe hydrops foetalis and over 75% haemoglobin Bart's, and their parents and living sibs. In the case of the hydropic babies, whose periods of gestation had varied from 32 to 38 weeks, cord or cardiac blood was examined. Iron deficiency was excluded in the parents of six of the seven families and the living sibs in Family 3 by the finding of normal serum iron levels ; in the remainder the haematological studies were carried out after at least one month of oral iron therapy. The haematological values of the mothers were those obtained after delivery. All parents were Rh-positive.

Standard haematological methods were used throughout. Red cell osmotic fragility was determined by the method described by Flatz, Pik, and Sringam (1965). The direct Coombs test was performed according to Dacie and Lewis (1963). Alkali-resistant haemoglobin was estimated (Singer, Chernoff, and Singer, 1951), and the amounts of haemoglobin A, A_2, and Bart's were determined by starch block electrophoresis at *p*H 8.6 (Kunkel, Ceppellini, Müller-Eberhard, and Wolf, 1957). In 56 control subjects the haemoglobin F levels were invariably less than 2% and the haemoglobin A_2 levels varied from 1.6 to 3.2%. Starch-gel electrophoresis at *p*H 7.0 was carried out according to Huehns, Flynn, Butler, and Shooter (1960) and at *p*H 8.6 according to Smithies (1959). Red cells were incubated with 1% brilliant cresyl blue at 37° C. for 30 minutes to detect haemoglobin H inclusions (Dittman, Haut, Wintrobe, and Cartwright, 1960), and at least 5,000 red cells were examined.



Pedigrees of the families of the seven hydropic babies.

Results

In the seven hydropic babies the necropsy findings were similar to those in the cases reported by Lie-Injo (1962). The haemoglobin levels varied from 3.3 to 10.0 (mean 7.4, S.D. 2.3) g./100 ml., and the blood smears showed markedly hypochromic red cells with anisopoikilocytosis, target formation, polychromasia, and numerous normoblasts. In only two instances (Families 1 and 3) were occasional red cells with haemoglobin H inclusions found. The amount of haemoglobin Bart's varied from 75 to 90% of the total haemoglobin (see Family Trees). The remaining 10 to 25% consisted of haemoglobin which migrated like haemoglobin A on starch block electrophoresis at *p*H 8.6 but was not seen in the position of haemoglobin A on starch-gel electrophoresis at *p*H 7.0. This fraction is being further studied by Dr. E. R. Huehns, of University College Hospital, London, and he has confirmed that the main haemoglobin fraction of the hydropic baby of Family 5 is haemoglobin Bart's. The alkali-resistant haemoglobin levels varied from 35 to 77% (mean 59.7%, S.D. 14.9%), and haemoglobin A_2 was not found in any. The direct Coombs test was negative in all, and three had the same ABO blood group as their mothers.

The haemoglobin levels in the seven fathers varied from 13.0 to 15.2 (mean 13.8, S.D. 0.7) g./100 ml., and in the seven mothers from 8.5 to 12.6 (mean 10.9, S.D. 1.1) g./100 ml. The red cells were hypochromic and showed decreased osmotic fragility in all except the father in Family 6.

The haemoglobin levels in the eight living male sibs varied from 9.8 to 12.5 (mean 11.7, S.D. 0.7) g./100 ml., and in the three living female sibs from 5.4 (a twin) to 13.0 (mean 10.2, S.D. 3.0) g./100 ml. The red cells were hypochromic and showed decreased osmotic fragility in all except two (Family 3, II 1 and 2).

Other details are set out in the accompanying Fig., in which only abnormal values of haemoglobin F and A_2 are shown. Subjects with normal or slightly decreased haemoglobin levels, hypochromic red cells, decreased red cell osmotic fragility, and normal amounts of haemoglobin F and A_2 are thought to be carriers of the α-thalassaemia trait (Weatherall, 1965). In four living sibs, all 4 months or younger, relatively small amounts of haemoglobin Bart's were found. No haemoglobin H inclusions were shown in the red cells of the parents or living sibs.

It will be seen that two parents (Family 6 I 1, Family 7 I 2) had slight but significantly raised levels of alkali-resistant haemoglobin which was thought to be haemoglobin F, as haemoglobin Bart's was not shown on starch-gel electrophoresis at *p*H 7.0. With these two exceptions, haemoglobin F levels were normal in the parents and in the seven living sibs aged 3 years or older, varying from 0.6 to 1.8% (mean 1.1%, S.D. 0.3%). In three parents (Family 5 I 1, Family 6 I 2, and Family 7 I 1) the haemoglobin A_2 levels were above normal, being 4.4, 4.0, and 6.5% respectively, while in the remaining parents and seven living sibs aged 3 years and older haemoglobin A_2 levels were normal, varying from 1.8 to 3.0% (mean 2.4%, S.D. 0.3%).

In Family 3, subjects II 5 and 6 were binovular twins, and subjects II 1 and 2 were haematologically normal. Sibs not studied included three neonatal deaths from unknown cause occurring two to four weeks after birth and one stillborn baby with hydrops foetalis in Family 4; one stillbirth in Family 5; two stillbirths with hydrops foetalis in Family 6; and two stillbirths and one neonatal death from unknown cause in Family 7.

Discussion

In Families 1 to 4 inclusive both parents showed haematological changes compatible with α-thalassaemia trait. Further, the living infants had small amounts of haemoglobin Bart's in addition to a mild thalassaemic blood picture. These findings are similar to those reported by Lie-Injo (1962) and Lie-Injo *et al.* (1962), and are consistent with the hydropic babies being homozygous for an α-thalassaemia gene. The relatively high level of haemoglobin Bart's of 23% in Subject II 2 of Family 1 is of particular interest, but unfortunately he has been lost to follow-up.

The finding in Families 5, 6, and 7 of three parents with high haemoglobin A_2 levels and two with increased haemoglobin F levels indicates the presence of β-thalassaemia trait and has not been previously reported among parents of similar hydropic babies. Since the combination of α-thalassaemia with either high or normal haemoglobin A_2 β-thalassaemia results in a mild thalassaemia only (Weatherall, 1965), it is unlikely that the hydrops foetalis was the result of double heterozygosity for α- and β-thalassaemia. The hydropic babies may have been, like those in Families 1 to 4, homozygous for α-thalassaemia, in which case the parents with the β-thalassaemia trait were by coincidence doubly heterozygous for α- and β-thalassaemia. However, the finding of a β-thalassaemia trait in 5 of 14 parents appears to be more than can be accounted for by chance. Further, the obstetrical histories of the mothers in Families 5–7 appear to be particularly bad, for in 13 pregnancies there were six stillbirths and two abortions in addition to the three hydropic babies (see Fig.). It is not clear what part the β-thalassaemia gene in the father of Family 5 had to play in the production of hydrops foetalis. However, in view of the report by Zuelzer, Robinson, and Booker (1961) that thalassaemia major may result when one parent has a high haemoglobin A_2 β-thalassaemia and the other a normal haemoglobin A_2, high haemoglobin F (4.3%) β-thalassaemia it is possible that the hydropic babies in Families 6 and 7 were the result of interaction between two β-thalassaemia genes and an α-thalassaemia gene, which, in the homozygous state, gives rise to hydrops foetalis. This hypothesis would be supported by the finding among living sibs either of increased levels of haemoglobin A_2 or F similar to those in the parents or of β-thalassaemia major, but unfortunately in the three families concerned out of 13 pregnancies there were only two living children.

The nature of this α-thalassaemia gene is not known, but it would appear to lead to a marked suppression of α-chain synthesis in the homozygous state. It is probably different from the α-thalassaemia gene in Negroes (Weatherall, 1965), as similar hydropic babies have not been reported among that race. It is also probably different from the "mild" α-thalassaemia gene of haemoglobin H disease (Huehns, 1965), which is usually not associated with red cell hypochromia, and, furthermore, haemoglobin H disease and hydropic babies with over 75% haemoglobin Bart's appear to occur in different families. It may be identical with the "severe" α-thalassaemia gene of haemoglobin H disease (Huehns, 1965). So far this severe α-thalassaemia gene has been reported only in Chinese (Lie-Injo, 1962), in Thais (Pootrakul *et al.*, 1966), and in Greek Cypriots (Diamond *et al.*, 1965), in all of whom haemoglobin H disease has also been encountered (Weatherall, 1965).

ADDENDUM.—Since the completion of this paper Kan *et al.* (1967) have reported a case of hydrops foetalis with large amounts of haemoglobin Bart's. The patient's father had an increased level of haemoglobin A_2.

Summary and Conclusions

Haemoglobin studies were carried out on the families of seven Chinese stillborn infants with severe hydrops foetalis and over 75% haemoglobin Bart's. Rh and ABO incompatibility were excluded.

There was evidence that five of the seven cases were the result of the homozygous state for α-thalassaemia. In the remaining two there was the possibility of interaction between an α-thalassaemia gene and a variety of β-thalassaemia major.

We are grateful to Dr. A. C. de Barros Lopes for referring Family 5 to us, and to Dr. John Grant for the serum iron determinations.

Preliminary Communications

Virus Antibodies in Subacute Sclerosing Panencephalitis: a Study of 22 Patients*

Brit. med. J., 1967, 3, 350–352

Subacute sclerosing panencephalitis was the term suggested by Greenfield (1950) to cover the subacute inclusion-body encephalitis described by Dawson (1933) and the subacute sclerosing leucoencephalitis of Van Bogaert (1945), as well as mixed forms. This has been accepted to some extent in the English literature (*B.M.J.*, 1965), but the earlier terms are still in use (Ulrich and Kidd, 1966; Dayan *et al.*, 1967). The histological appearances of the condition certainly differ from case to case, but they may also vary during the evolution of the disease; in an example reported by Schiøtt (1959) inclusion bodies were found in brain biopsy material obtained six months from the onset of symptoms, but not in post-mortem material two months later. At present, therefore, the condition cannot be clearly subdivided on histological grounds.

The inclusion bodies suggest that the disease might have a viral origin, but until recently there was no evidence to incriminate any particular virus. However, in 1965 Bouteille *et al.* published electronmicrographs of biopsy material, and the appearances of the inclusions were strikingly similar to those of measles virus grown in dog-kidney-tissue culture (Tawara, 1965). Tellez-Nagel and Harter (1966) and Dayan *et al.* (1967) have published similar pictures from other cases. Connolly *et al.* (1967) have described the presence of measles complement-fixing and haemagglutination-inhibiting antibodies in the serum and C.S.F. of three cases, and have demonstrated fluorescence in post-mortem brain material treated with fluorescein-labelled measles antiserum.

As part of a virological investigation into encephalitis we have examined sera from patients with subacute sclerosing panencephalitis for the presence of viral antibodies. Measles antibody was present in all cases, often in high titre. This report compares the results of serological tests for measles and other viral antibodies in patients and controls.

PATIENTS AND METHODS

We were able to study 22 patients (16 males and 6 females) referred to this department for investigation. One of them was also studied by Connolly *et al.* (1967). Their ages at the onset of neurological symptoms ranged from 5 to 18 years (Table I). Some of them were included in the clinical report of Metz *et al.* (1964); all were observed to suffer from typical repetitive movements, and all had at least two of the following features: convulsions, intellectual deterioration, behavioural disorder, and impaired motor function. The C.S.F. Lange test gave a paretic rise in all but two cases, in one of which it was not performed. All but one had the characteristic E.E.G. changes (Cobb and Hill, 1950). Confirmation of the diagnosis by pathological examination of biopsy or post-mortem material, or both, was obtained in 14 cases, including one with an uncharacteristic E.E.G. and the one in which the Lange test was not done; inclusion bodies were found in eight. Serum was available from all 22 patients, and C.S.F. from nine of them.

Serum was also available from 23 control subjects (13 males and 10 females) of the same age range as the patients (Table I). None suffered from any sort of progressive neurological disease, and they were referred to this department for investigation of childhood infectious diseases, such as gastroenteritis or aseptic meningitis, or for screening for rubella antibodies. None was known to suffer from immunological deficiency.

TABLE I.—*Age and Sex Distribution of 22 Patients and 23 Controls*

		Age in Years													
		5	6	7	8	9	10	11	12	13	14	15	16	17	18
Patients	M	1			1	1	3	3	1	1		2		2	1
	F		2				1	1	1				1		
Controls	M	2	1	1		1	3	2	2			1			
	F		2	1	1		1	2	1	1					1

Before examination sera and C.S.F. specimens were stored at −20° C. for periods of up to six years.

COMPLEMENT-FIXATION TEST FOR MEASLES AND OTHER VIRAL ANTIBODIES

The sera were diluted 1:10 in veronal-buffered saline and inactivated at 56° C. for 30 minutes; two of the patients' specimens proved anticomplementary and required a further 30 minutes' heating. Serial twofold dilutions were then made from 1:10 to 1:2,560. The C.S.F. specimens were not inactivated; they were tested undiluted and in serial twofold dilutions up to 1:32. Antigens and control antisera were kindly provided by the Standards Reference Laboratory at Colindale, except for the herpes antigen, which was made in this department from a strain of herpes simplex cultured in a continuous line of rabbit-kidney cells (RK-13). The test was performed by means of a microtechnique on perspex plates, four units of antigen and two units of complement being used. Fixation was allowed to take place overnight at 4° C., and the following day two volumes of 0.4% sensitized sheep red cells were added. The endpoint of the titration was taken as the highest dilution showing complete or almost complete fixation of complement.

Complement-fixation tests on patients' sera and control sera were performed on different days; a positive antiserum and three of the patients' sera were tested on both occasions, the results agreeing to within one dilution. Serum and C.S.F. pairs were titrated together in five cases and separately in four with identical antiserum results.

HAEMAGGLUTINATION-INHIBITION TEST FOR MEASLES

The sera were diluted 1:2 in normal saline and were then absorbed with 25% kaolin for 20 minutes at room temperature, and with 50% Patas red cells overnight at 4° C. The dilution of the specimens after treatment was taken as 1:4 and serial twofold dilutions were prepared from 1:8 to 1:2,048. Four sera were available only at a dilution of 1:10, at which they had been stored for three weeks; they were absorbed in a similar way and diluted from 1:20 onwards. The C.S.F. specimens were not absorbed; they were serially diluted up to 1:32. Haemagglutinating antigen was prepared in this laboratory from an Edmonston B strain of measles virus kindly supplied by Glaxo Laboratories Limited, and was treated with Tween 80 and ether before use. Eight haemagglutinating doses were used, and the test was carried out by a microtechnique in Takatsy plates. Specimens of serum and C.S.F. were

---

* Supported by a grant from the National Fund for Poliomyelitis Research.

allowed to react with antigen at room temperature for two hours; one volume of 1% Patas cells was then added and the plates were incubated at 37° C. until the cells had settled—that is, for about 45 minutes. The endpoint of the titration was taken as the highest showing complete or almost complete inhibition of agglutination.

All save one of the patients' sera and all the control sera were tested for haemagglutination-inhibiting antibody together on the same day. Five of the serum/C.S.F. pairs were titrated together, and two were done separately; there was insufficient C.S.F. for testing from the remaining two.

RESULTS

The measles complement-fixing and haemagglutination-inhibiting antibody titres in patients and controls are shown in Tables II and III. Where more than one serum was available from a patient the first specimen has been recorded, except for one haemagglutination-inhibition result, where the second specimen has been recorded because the first had been stored at 1:10 dilution; this can cause a fall in titre. The antibody levels in the patients are much higher than in the controls, and the differences are highly significant: grouping the complement-fixing antibody levels into those of 80 and above and those below 80, $\chi^2=30.35$, $P<0.01$; similarly, grouping the haemagglutination-inhibiting antibody levels into those of 64 and above and those less than 64, $\chi^2=9.79$, $P<0.01$. The patients' levels are comparable to those we have found in convalescent measles patients when using the same technique.

No. of patients			2	1	2	1	3	2	6	2	3
„ „ controls	2	4	7		4		6				

Because patients and controls are not precisely matched for age and sex, the results have been examined for correlation with both these variables for patients and controls, and there is no correlation with either.

Tables IV and V give the antibody levels of patients in whom a neuropathological examination was made, divided into those with inclusion bodies and those without. There is no difference in complement-fixing antibody levels between these groups, and, though haemagglutination-inhibiting antibody levels are higher in the patients with inclusions, the numbers are small and the difference falls short of statistical significance (by Yates's method $\chi^2=3.22$, $0.1>P>0.05$).

Figs. 1 and 2 show complement-fixing and haemagglutination-inhibiting antibody titres in relation to the duration of neurological symptoms. No correlation is seen and there is no significant rise in titre in the serial specimens available.

The results of complement-fixation tests against other virus antigens are shown in Table VI. Herpes antibody is present with significantly greater frequency in patients than in controls, but 11 patients had no demonstrable herpes antibody. There is no difference in the incidence or titre of other antibodies.

Measles complement-fixing antibody was demonstrated in the C.S.F. in five out of nine patients tested and haemagglutination-inhibiting antibody in seven out of seven. Herpes complement-fixing antibody could be found in only two out of nine. The serum complement-fixing antibody levels obtained in the simultaneous serum and C.S.F. tests were considerably lower than on several previous estimations, owing to deterioration with storage, so an accurate C.S.F./serum ratio cannot be calculated.

DISCUSSION

These investigations have revealed abnormally high titres of both complement-fixing and haemagglutination-inhibiting measles antibodies in the serum of 22 patients with subacute sclerosing panencephalitis. Such titres are usually found only in the convalescent phase of measles, after which complement-fixing antibody declines rapidly and haemagglutination-inhibiting antibody more slowly (Krugman *et al.*, 1965). In one of our patients the neurological illness may have begun with an attack of measles which occurred at the age of 8 months and was complicated by corneal ulceration; her legs became spastic soon afterwards and her subsequent development was retarded, but the full picture of subacute sclerosing panencephalitis was not seen until five years later. However, the remaining 16 patients from whom a history was available had had uncomplicated attacks of measles which preceded their encephalitis by intervals of 3 to 14 years.

Abnormally high titres of measles antibody have also been found in the serum of patients with multiple sclerosis (Adams and Imagawa, 1962; Reed *et al.*, 1964; Clarke *et al.*, 1965), and this has not yet been explained. In subacute sclerosing encephalitis, however, the supporting evidence of electron-microscopy and immunofluorescence justifies the suggestion that measles, or an antigenically related virus, is the cause of the disease. If this is so three possible mechanisms can be considered.

Firstly, measles virus might have entered the central nervous system at the time of the original attack and remained latent there for some years before being reactivated and producing disease. This would be analogous to the generally accepted pathogenesis of varicella-zoster infection in man, and to the deferred encephalitis which can be produced experimentally in rabbits infected with herpes simplex (Good and Campbell, 1948; Schmidt and Rasmussen, 1960). There is a certain amount of evidence that the central nervous system can be involved in natural measles infection. In uncomplicated cases Ojala (1947) found pleocytosis in the C.S.F. in some instances, and Pampiglione (1964) discovered E.E.G. abnormalities in all cases tested. Adams *et al.* (1966) described measles-type inclusions in the brains of patients who had died of acute measles encephalitis. Thus the virus often affects the nervous system in some way, and may gain entry to it in certain circumstances. There is support for the concept of latency in the work of Enders-Ruckle (1965), who reported the isolation of measles virus from lymph nodes and spleen some years after measles infection. At present, however, there is no other recorded example of latent infection with measles or with any other ribonucleic acid virus.

Secondly, the disease may be caused by reinfection with measles in an already immune or partially immune person. It is generally accepted that immunity to measles is long-lasting, but this is based on the fact that second attacks of measles with a rash are exceedingly rare, and the sustained immunity may itself be the result of repeated subclinical infection (Krugman *et al.*, 1965). We have not found any history of exposure to reinfection in our cases.

Thirdly, the disease may be due to a virus related to measles, such as canine distemper virus, which can certainly produce a subacute as well as an acute neurological disease in dogs. At present these two viruses cannot be clearly differentiated on the basis of serum antibodies, immunofluorescence, or electron-microscopy. One of our patients had a pet ferret which died just before his encephalitis began, but we have found no other history of specific contact with animals likely to have been suffering from distemper virus infection.

With any of these mechanisms one would expect the antibody titre to rise in the early stages of the neurological disease, unless latent measles infection had provided a continuing stimulus to antibody production ever since the original attack of measles. We do not know whether these patients' antibody levels were normal in the interval between their original attack and the onset of their encephalitis, and we have not demonstrated a significant rise in titre with progress of the disease. However, in only one case was a specimen of serum obtained in the first month of illness, so that an early rise could have been missed. We have not found any parallel to the case described by Connolly *et al.* (1967) in which the antibody titres rose markedly over a period of 10 months. The mortality rate in this condition is of course high, but in three of our patients the disease has become arrested, and in one there has been a good recovery after about a year's illness. Four years after recovery this patient's complement-fixing antibody level has fallen to an undetectable level, but haemagglutination-inhibiting antibody has not altered significantly.

There is now evidence that measles-like virus particles and virus antigen are present in the brain in this disease, but despite many virological experiments the virus has never been isolated from brain tissue. This situation may be analogous to the experimental work of Rustigian (1962), who described a chronic measles infection in HeLa cells; the infection could be demonstrated by the presence of typical inclusion bodies, specific immunofluorescence, and complement-fixing antigen, but the virus could not be passaged to other tissue cultures.

SUMMARY

Measles complement-fixing and haemagglutination-inhibiting antibodies have been found in the serum of 22 patients with subacute sclerosing panencephalitis in significantly higher titre than in controls. These findings support the results of electron-microscopy and immunofluorescence in suggesting that the disease is due to a measles-like virus. The evidence does not at present enable us to differentiate between a latent measles infection which has become reactivated, a reinfection with measles, and a primary infection with a related agent such as canine distemper virus.

I would like to express my thanks to Dr. J. A. Dudgeon for his advice and encouragement; to Mr. A. I. Fraser and Mr. G. T. Hawkins for their technical work; to the National Fund for Poliomyelitis Research for financial support; and to the Standards Reference Laboratory and Glaxo Laboratories Limited for reagents.

Medical Memoranda

Diffuse Systemic Sclerosis with Abnormal Liver and Gall Bladder

Brit. med. J., 1967, 3, 353–354

A case of diffuse systemic sclerosis is described in which the gall bladder was involved in the sclerotic process, an occurrence not previously noted.

CASE HISTORY

A woman aged 51 was seen at St. Thomas's Hospital by Dr. H. J. Wallace in 1963 with a five-year history of generalized pruritus. One year previously she had suffered an impacted fracture of the neck of the right humerus with separation of the greater tuberosity. This healed satisfactorily, but despite physiotherapy the arm lost much of its usefulness because of the rapid development of tightness of the skin of that arm and hand. She had had Raynaud's phenomenon in both hands and feet. On examination advanced scleroderma of the right forearm and hand and widespread guttate scleroderma, mainly of the upper arms and shoulders, were present, along with a generalized increase of pigmentation. There were many telangiectases of face, lips, buccal mucosa, tongue, and both hands—important physical signs of diffuse systemic sclerosis (Johnston *et al.*, 1965).

She had had infectious hepatitis at age 17, being jaundiced for two weeks. Stasis eczema of the leg had occurred at age 35 after an operation for varicose veins. Later she had developed contact eczema due to hypersensitivity to an antihistamine cream. She did not drink alcohol and had had no drugs known to cause liver damage.

Haemoglobin was 82% and E.S.R. (Westergren) 105 mg. in one hour. No L.E. cells were seen in the peripheral blood. Serum antinuclear factor was negative. Serum protein electrophoresis showed raised alpha-2, beta, and gammaglobulins. Serum creatine was 1 mg./100 ml. The blood urea and creatinine clearance were normal. The formiminoglutamic acid test was slightly positive. Fatty-acid excretion in a five-day stool save averaged 6.7 g./24 hours. E.C.G. and chest *x*-ray picture were normal. A supine barium swallow and meal showed normal oesophageal peristalsis and no oesophageal varices, but a hiatus hernia was present with free gastro-oesophageal reflux.

In October 1964 she was admitted to Kingston Hospital with shortness of breath and anginal pain on exertion. She had had melaena for the previous week and had recently had heartburn associated with regurgitation of bitter fluid. On examination she was very pale, with a raised jugular venous pressure, sacral oedema, and bilateral basal crepitations. The liver was enlarged and firm.

Her haemoglobin was 33% and M.C.H.C. 24%. The red cells showed extreme hypochromia. The E.S.R. was 149 mm. in one hour. Sternal marrow showed normoblastic hyperplasia and no free iron could be demonstrated. No L.E. cells were seen in the peripheral blood. Serum calcium was 9.8 and phosphate 4.2 mg./100 ml. The serum vitamin B_{12} was 600 μμg./ml. Liver-function tests showed bilirubin conjugated and total 0.75 mg./100 ml., thymol turbidity 6.0 units, serum cholesterol 270 mg./100 ml., alkaline phosphatase 95 units, aspartate transaminase 68 units, alanine transaminase 57 units, and total serum proteins 8 g./100 ml. (albumin 4 g., globulin 4 g.). Electrophoresis showed increased gammaglobulin. Prothrombin index was 100%. Electrophoresis of the alkaline phosphate enzyme suggested an origin from liver rather than bone. The histidine loading test was figlu-positive. Four specimens of stool were positive for occult blood, and two separate three-day collections of stool showed an average fatty-acid excretion of 3 and 4.8 g./day respectively. Barium-meal examination showed no dilatation or delay in the oesophagus, but free oesophageal reflux and a sliding hiatus hernia were present. No oesophageal varices were seen. The stomach, duodenum, and small bowel were normal.

A diagnosis of bleeding from the hiatus hernia was made and oral iron and folic acid were given. Six weeks later the haemoglobin was 75%.

In view of the abnormal liver-function tests a cholecystogram was taken; this showed poor concentration of the contrast medium in spite of a double dose. Good contraction of the gall bladder occurred after a fatty meal. No opaque calculi were seen, but some small non-opaque stones were suspected in the fundus. Aspiration liver biopsy: serial histological sections showed diffuse infiltration of the portal tract by moderate numbers of mixed inflammatory cells; to a small extent this exudate involved the adjacent parenchyma, which was otherwise normal. Because of the possibility of extrahepatic biliary obstruction laparotomy was performed by Mr. W. J. D. Bradfield. The liver was very nodular and the spleen enlarged. The gall bladder was yellowish but contained no calculi. The common bile duct was normal and a cholangiogram via the cystic duct was normal. Cholecystectomy and liver biopsy were performed. The gall bladder was 9 cm. long and its wall was thickened and oedematous. Microscopy showed an intact mucous membrane, but there was a considerable degree of fibrosis of the serosa without obliterative endarteritis, suggesting that the fibrosis was more likely to be part of a diffuse systemic sclerosis than to be due to chronic cholecystitis. The liver biopsy revealed the histological appearances of an early but uniform fibrosis, most pronounced in the portal tracts but also spreading out into the parenchymal tissue (Figs. 1 and 2).

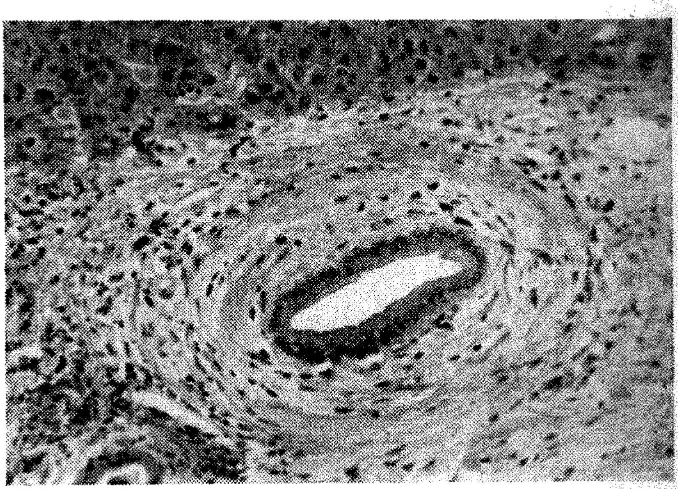

FIG. 1.—Liver, showing fibrosis round bile ductule and moderate chronic inflammatory changes. (H. and E. ×80.)

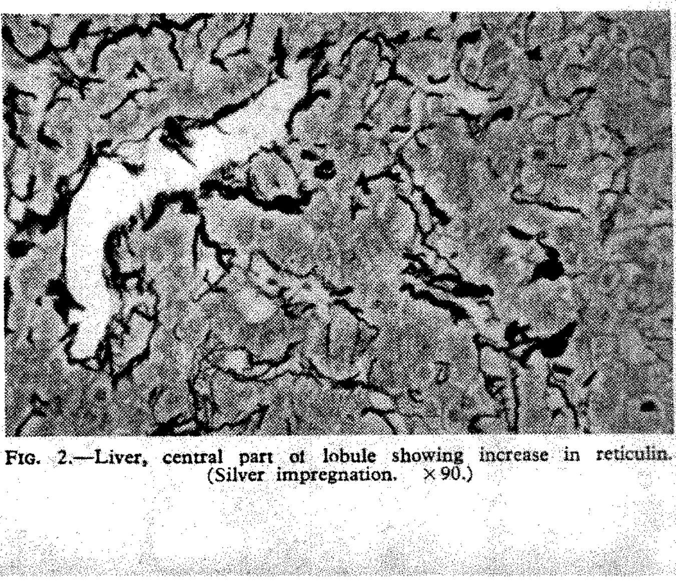

FIG. 2.—Liver, central part of lobule showing increase in reticulin. (Silver impregnation. ×90.)

The patient made a good recovery from the laparotomy. However, during the next year her spleen became intermittently palpable and she was slightly jaundiced. Liver-function tests on 8 October 1965 resulted as follows: bilirubin conjugated 1.3 mg./100 ml., total 1.5 mg., thymol turbidity 4.0 units, serum cholesterol 335 mg./100 ml., alkaline phosphatase 110 units, aspartate transaminase 88 units, alanine transaminase 96 units, total serum proteins 7.3 g./100 ml. (albumin 3.8 g., globulin 3.5 g.). Electrophoresis showed increased gammaglobulin.

DISCUSSION

The two unusual features in this patient were the rapid progression of the scleroderma of the arm after fracture of the humerus and the involvement of the liver and gall bladder. The only other reference we have found to trauma apparently influencing scleroderma is made by Zarafonetis (1964). In that case scleroderma of the left arm developed after a cut on the hand.

In view of the histological appearances there is little doubt that the abnormal gall bladder in the present case was due to involvement by the sclerotic process. Such involvement has not to our knowledge been previously described, though acute arteritis and periarteritis in the gall bladder were mentioned in one case by Leinwand *et al.* (1954). The liver involvement in the present case seems also to be related to the scleroderma, but it is impossible totally to exclude its being a sequel of the previous hepatitis. The histological features, however, are atypical for this, and the involvement of the gall bladder further diminishes this possibility.

Some previous accounts of liver abnormalities in scleroderma were summarized by Tuffanelli and Winkelmann (1961) and by Bartholomew *et al.* (1964), and in the latter series of 727 cases of scleroderma a "severe non-specific cirrhosis of unknown aetiology" was present in four. Other references include three examples of "focal necrosis" and one of portal cirrhosis (Piper and Helwig, 1955) and one of chronic biliary cirrhosis (Goetz, 1945), but histological details are insufficient to compare these with the present case. The histological changes in the case described by Batsakis and Johnson (1960), however, are very similar to those in the case we describe. But in two cases reported by Beigelman *et al.* (1953) the changes affected the centre of the hepatic lobule and were dissimilar.

Calvert *et al.* (1958) reported two cases of systemic scleroderma and hepatic fibrosis which bled from oesophageal varices. Treacy (1960) recorded hepatic failure as the cause of death in one patient. Though involvement of the hollow viscera in some degree is probable in most cases (Haubrich, 1965), liver involvement in scleroderma is undoubtedly rare. No cases were seen among 150 patients investigated by Leinwand *et al.* (1954), and none was discovered in the review of the literature by Goldgraber and Kirsner (1957). In addition, it is not mentioned in standard textbooks on liver disease (Kleckner, 1960; Popper and Shaffner, 1961; Sherlock, 1963; Schwartz, 1964) or in books on connective-tissue disorders (Richardson, 1963) or on skin pathology (Allen, 1954; Lever, 1961). It is therefore essential that detailed histology should be reported in all future cases, so that an attempt may be made to establish finally whether such involvement is aetiologically related, and, if so, what is the characteristic macroscopic and microscopical pattern.

Similarly, a catalogue of liver-function tests in future cases might reveal a diagnostic spectrum. The present case showed a striking pattern with a grossly raised serum alkaline phosphatase, a moderate rise in serum transaminases, and very slight rises in the thymol turbidity and bilirubin. It is known that scleroderma alone does not produce abnormal liver-function findings, though the serum gammaglobulin is often increased (Stáva, 1958).

Our thanks are due to Dr. H. J. Wallace for advice, to Dr. M. E. A. Powell for much help with the pathology, and to Mrs. Eileen Walsh for secretarial assistance.

Current Practice

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Sodium Chloride and Renal Calculi

Q.—*What is the rationale of giving sodium chloride regularly to prevent the formation of renal calculi in those prone to them?*

A.—The solubility of calcium phosphate and calcium oxalate is a function not so much of the concentrations of their constituent ions in the medium (be it urine or simple electrolyte solution) but of the activities of these ions. The activity coefficient of an ion is inversely related to ion strength, and the higher the concentration of, for instance, sodium chloride in urine the lower will be the activity coefficients of the calcium, phosphate, and oxalate ions and the higher the solubility of the stone or precipitate. In practice, the effect of urinary ion strength on stone solubility is of little significance at ion strengths over 0.15 but may be of some practical importance at ion strengths below this value.

Relying on this consideration, Udall[1] has shown that urinary calculi in lambs can be controlled by force-feeding of sodium chloride. Modlin[2] has also emphasized the effect of sodium on apatite solubility, and suggested that stone formation is rare when the sodium/calcium ratio in the urine is high. However, the high sodium/calcium ratios in non-stone-forming populations to which he draws attention are as much due to a low urinary calcium as to high urinary sodium.

It would be premature to advocate the treatment of renal stone disease with sodium chloride feeding at the present time.

Sialagogues in Sjögren's Syndrome

Q.—*What satisfactory sialagogues, apart from pilocarpine, are available for a patient with Sjögren's syndrome?*

A.—Sjögren's syndrome is a particularly distressing affliction, for its treatment is so unsatisfactory. Methylcellulose artificial tears help to overcome symptoms due to keratoconjunctivitis sicca. Sulphacetamide eye-drops and ointment minimize bacterial complications, including corneal ulceration. Because of their bland alkalinity, these eye-drops are also soothing. Sealing of the puncta by cautery helps to conserve what little moisture is present.

Since Sjögren's syndrome is commonly in women aged between 40 and 50, oestrogens might be helpful. The association is strengthened by the fact that hydroxyproline excretion is greatly increased in those suffering from the syndrome, and this biochemical abnormality can be corrected by oestrogens. Since Sjögren's syndrome is regarded as an autoimmune phenomenon similar to systemic lupus erythematosus and to primary biliary cirrhosis, immunosuppressive drug regimens are sometimes used. Local and oral corticosteroids have been given and even azathioprine considered, but relapses follow cessation of treatment and the danger of corneal ulceration is always present with such regimens. Because of the similarity to lupus erythematosus, chloroquine has been tried and found more effective than a placebo in a double-blind trial.

Patients with Sjögren's syndrome are often depressed. The affliction may be sufficient to account for this, but there could also be an element of endogenous depression for which nortriptyline or imipramine is indicated. Contact lenses may give relief. Every patient has his own favourite prescription for overcoming dryness of the mouth. Polo mints seem to be favoured as much as anything.

Liquid Paraffin as Carcinogen

Q.—*Is there any evidence that the regular use of liquid paraffin or preparations such as petrolagar may cause carcinoma in the gastro-intestinal tract?*

A.—Medicinal liquid paraffin is a highly purified product. Nevertheless, Druckrey and his colleagues[1] thought that purification may not entirely remove all the carcinogens shown to be present in crude mineral oils.[2] Boyd and Doll[3] found an appreciable excess among patients with gastrointestinal cancer of a history of the use of liquid paraffin. There was no excess in the use of laxatives of other types nor in the overall use of purgatives among such patients as compared with patients suffering from diseases other than of the gastrointestinal tract. For various reasons, these authors did not feel that this evidence indicated that liquid paraffin is more than very weakly carcinogenic.

Reaction to Triple Antigen

Q.—*What dosage of adrenaline is recommended for the emergency treatment of collapse after injection of triple antigen in infants aged 3-to 12 months? Is an injection of a corticosteroid a better treatment in this situation?*

A.—Most pertussis vaccines produce a slight rise in temperature and an associated mild degree of irritability within one to eight hours of injection. These reactions are particularly common and more severe after quadruple vaccines (D.T.P./Polio) and pertussis vaccines prepared from organisms grown in liquid media.[1]

Collapse is one of the rarer and more alarming of the reported reactions. It has a sudden onset one to four hours after immunization and lasts from one-half to one hour, but recovery is usually complete within 24 hours. Its main features are marked pallor, cold skin, hypotension, and general physical collapse. It is not an anaphylactic reaction nor is it due to any other immunological phenomenon.

Since the reaction resembles shock induced by injected endotoxin from Gram-negative bacteria it is inadvisable to treat it with adrenaline. Corticosteroids are more likely to be effective and less likely to aggravate the condition. When, therefore, the condition gives rise to immediate concern the administration of corticosteroids should be considered.

Glycosuria after Myocardial Infarction

Q.—*What is the explanation for a period of glycosuria that frequently seems to come after a myocardial infarction?*

A.—Glycosuria after a cardiac infarction is due to a raised blood sugar, which in turn may be caused by a number of factors such as an excess adrenaline producing glycogenolysis, considerable mental and physical stress increasing adrenal cortical activity and gluconeogenesis, and a decreased capacity of the liver to handle carbohydrate, due to a fall in hepatic blood flow. There is also evidence that many people who have cardiac infarcts are latent or potential diabetics. The stress during an acute infarct then precipitates carbohydrate intolerance for a short period, and it is analogous to the principle of the steroid-loaded test for prediabetes.

Preventing Scarring in Chicken-pox

Q.—*What is the best treatment in a case of chicken-pox to minimize the risk of subsequent scarring when the pustules have healed?*

A.—The chicken-pox lesion is situated in the middle and deeper layers of the epidermis. Except in very severe cases, there is very little inflammatory change in the corium, so that when the scab separates a normal re-epithelized surface is left behind. The risk of scarring is therefore very slight in uncomplicated chicken-pox. Deeper penetration may occur if the lesions become secondarily infected. The pus should be cultured and the appropriate antibiotic or other drug given by mouth. Local applications do more harm than good.

Book Reviews

Cerebrospinal Fluid

Physiology of the Cerebrospinal Fluid. By Hugh Davson, D.Sc.(Lond.). (Pp. 445+vii; illustrated. 84s.) London: J. & A. Churchill. 1967.

Dr. Hugh Davson's previous volume *The Physiology of the Ocular and Cerebrospinal Fluids*, published ten years ago, is well known to both neurologists and ophthalmologists. As he points out in his preface to his new book, there have been many papers in recent years on experimental studies of the formation and circulation of cerebrospinal fluid, and he therefore wisely decided that a new volume devoted exclusively to the cerebrospinal fluid was necessary. In this work he studies in turn morphological aspects of the fluid, its chemical composition and secretory nature, and the blood–spinal-fluid and blood–brain barriers. He has also devoted space to considerations of the extracellular space of the brain and cord, as well as to acid–base balance, the control of respiration, and the influence of these and other factors on cerebrospinal-fluid pressure. The book is carefully and logically arranged. The illustrations are in general of outstanding quality and consist in part of excellent graphs and line drawings, but in addition there are many half-tone illustrations of radiographs, photomicrographs, and electronmicrographs which add considerably to the value of the work.

In parts the text is so technical and highly concentrated that the book does not always make easy reading, but nevertheless it is one that repays careful study, as it is a mine of information, and it is difficult to imagine that anything of importance concerned with the cerebrospinal fluid has been omitted. Though its title suggests that it is a study of the physiology of the fluid, there are substantial sections devoted to pathophysiology and to the changes which occur in disease. There is also a full bibliography and a comprehensive index, so that the work is an excellent source of reference. Without question this book will become the standard work on the cerebrospinal fluid. The author is to be congratulated on the orderly format and scope of this scholarly monograph, and the publisher on the standard of production.

JOHN N. WALTON.

Mind and Brain

The Memory System of the Brain. By J. Z. Young. (Pp. 128+vi; illustrated. 28s.) London: Oxford University Press. 1967.

This short book comprises the Hitchcock lectures delivered by Professor Young at the University of California in 1964, and presents a readable and penetrating account of the way this distinguished biologist views the neural basis of memory at this moment in the history of its investigation. Based in essence on his well-known work on the Neapolitan octopus, it affords a splendid justification for the years of patient study the author has devoted to this unprepossessing cephalopod. The octopus was chosen for the experimental analysis of memory because of the simplicity of its sensory equipment and its motor repertory, but Professor Young transcends so limited a brief. His lectures go some way towards bridging the critical gap between neurology and psychology. They range widely over the more general implications of his experimental studies, and abound in original and arresting speculations.

To select from the author's many felicitous ideas a few which indicate the flavour of the book is not easy, but the reviewer was intrigued by his concept of evolutionary survival through the arrangement by which the body machine, discarded on the death of the individual, is perennially rebuilt from the "code of instructions" handed on, with amendments, at each reproductive cycle. In human memory also a complex neural organization, and a relatively long life that affords scope for extensive learning experience, are reinforced by man's development of information stores outside himself that endow him in this connexion with what the author aptly describes as a "multiparental inheritance."

Throughout the book Professor Young employs the ideology and the language of computer science to describe the working of the brain in recording, storing, and recalling discrete items of memory, but he goes far beyond the cruder analogies so often drawn in this connexion, and even at our present early and fragmentary stage of knowledge in this field he maintains a firmly biological orientation.

This illuminating and thoroughly enjoyable study emphasizes the fatuity—if indeed it requires emphasis—of the artificial division between structure and function that is perpetuated in the continued existence of independent departments of anatomy and physiology in medical schools and universities. It also furnishes comforting evidence that there are neurophysiologists of distinction who devote their genius to studying the behaviour of the whole organism and not merely of the isolated cell. To paraphrase its author, the content of a book furnishes more interesting material for study than the chemical composition of printer's ink.

HENRY MILLER.

Clinician and Bacteriologist

The Clinical Practice of Bacteriology. By Kevin Anderson, M.D.(Lond.), M.R.A.C.P., M.C.P.A., M.C.Path. (Pp. 243+x; illustrated. 42s.) Oxford: Blackwell. 1966.

This short well-written book is intended to bring the clinician and clinical bacteriologist closer together. Improved appreciation of one another's work and problems should result in better use of the laboratory to the ultimate benefit of clinician and bacteriologist, and, most of all, the patient. These important sentiments will be endorsed by many; but beyond advertising them I am not sure how the book will further them.

My greatest difficulty has been in identifying the audience Dr. Anderson had in mind. It was evidently not clinical bacteriologists. Apart from the fact that 100% sales to them would hardly make a best seller, the bacteriology is largely elementary. Evidently it was not clinicians either. The accounts of infectious diseases are largely those of the textbooks. If we safely assume that the book is intended for the student of clinical bacteriology (in the widest sense), it suffers from being written at a number of levels. Although most of it is elementary, it assumes some existing knowledge of bacteriology and medicine and there are references to more complicated matters of which some are mystifyingly brief.

The main difficulty for the student is that the book is in no sense a textbook. It is not comprehensive and the choice of material is arbitrary. For example, under the heading "non-bacterial meningitis" there appears only an account of meningeal infiltration in Hodgkin's disease and leukaemia. There is a table showing all the concentrations of antibacterial agents to be incorporated in media used for testing the sensitivity of *Myco. tuberculosis*, but beyond a mention there is no account of atypical mycobacteria. The references are few, often old, and usually support some relatively minor matter. It is, in a word, a highly personal book and is enlivened by personal case histories. Accepted as such, it makes interesting and enjoyable reading. Whether this is sufficient recommendation to ensure its reaching a wide enough audience to secure the author's admirable objective remains to be seen.

F. O'GRADY.

X-ray of the Abdomen

Radiographic Examination in Blunt Abdominal Trauma. By James J. McCort, M.D. (Pp. 252+viii; illustrated. £3 13s. 6d.) London: W. B. Saunders. 1966.

Dr. McCort, Professor of Radiology in Stanford University Medical School, has gathered together in one volume many and diverse *x*-ray signs of injury to the abdomen and its contents, signs that it would be difficult to run to earth in the many standard textbooks of diagnostic radiology. This book has therefore a particular value to those clinicians and radiologists who are engaged in the running of casualty departments.

The first 50 pages are devoted to the appearances in the plain *x*-ray film of the normal and injured abdomen. Mention is made of the pioneer work of Frimann-Dahl in the *x*-ray study of the abdominal wall in health and disease. This section is probably the most important, since every abdominal casualty should have at least a plain film taken of the abdomen, and much can be learnt from it—haemorrhage, rupture of a solid or perforation of a hollow viscus, or mere injury to the abdominal wall.

A short section outlines special *x*-ray procedures—barium and Gastrografin alimentary studies, pneumoperitoneography, abdominal arteriography, and urography.

The rest of the book is devoted to a detailed study of the *x*-ray signs of injury to the various abdominal organs; the spleen (it is the commonest), liver, gastrointestinal tract, pancreas, kidney, and bladder. It contains a wealth of information in a commendably concise form and is warmly recommended to those who are engaged in this work.

S. COCHRANE SHANKS.

Range and Concepts of Epidemiology

Clinical Epidemiology. Revised edition. By John R. Paul. (Pp. 305+xix; illustrated. 56s.) London: University of Chicago Press. 1966.

This book is a volume in the series "The Scientist's Library: Biology and Medicine." The purpose of this series is to provide information not only for the expert but also for workers in various fields of biology and medicine on developments which have occurred in recent years in subjects which lie outside their own specialty. The book is not a textbook in the usually accepted sense, but rather a review of the range and concepts of epidemiology. These have been discussed in three sections: principles, definitions, and history; methods and uses; and sample diseases. Problems in public health, social, preventive, and industrial medicine are used as examples of the epidemiological approach, but no attempt has been made to introduce any statistical or mathematical methods of analysing data.

The first edition of this book was mainly confined to the epidemiology of infectious diseases, but this edition includes non-infectious diseases such as coronary artery diseases and cancer. Influenza, except for a brief note on outbreaks among Eskimos, has not been discussed, and this is rather surprising in view of the vast amount of work which has been done both in America and Britain. Each chapter is followed by a bibliography; the number of papers to which the reader is referred varies from three to 50, but some of the references occur at the end of more than one chapter. As might be expected in an American book, most of the papers referred to were published in America—for example, slightly over three-quarters of the 49 references following the chapter on infectious serum hepatitis were American publications, and many good British and Continental investigations are not mentioned.

The conditions under which investigations are carried out in the United States differ in some respects from those in England. The methods of population sampling used in the American inquiries is not applicable to Britain, since we do not have "census tracts." The use of questionaries is perhaps easier in America, where the population has been conditioned to form-filling. The difficulty of defining a perinatal death rate is purely an internal affair, since every state determines what should be considered a foetal death. In England a stillbirth must be of 28 weeks gestation, while in the United States the general rule is that foetal deaths over 20 weeks are registered as stillbirths, but this period varies between states, and in some states all products of conception must be registered, even miscarriages at eight weeks.

In a revised edition it seems strange that a typographical error should occur twice: Newcastle upon Tyne is referred to as New Castle-upon-Tyne. The index to the book is not complete and it appears to be a matter of chance whether the name of an author quoted in the text appears in the index.

The questions that a new book poses are: Is there a place for another book on this subject, and, if so, has the author fulfilled this need? With this book the author has succeeded in his main aim of presenting for the general reader a broad and interesting description of the concepts of epidemiology and the range of subjects that have been studied and the problems involved. Not only the amateur but investigators and teachers of epidemiology will find this book interesting and profitable.

W. J. MARTIN.

Edinburgh School

The Principles and Practice of Medicine. 8th edition. By Sir Stanley Davidson, B.A.Cantab., M.D., F.R.C.P.Ed., F.R.C.P. Lond., M.D.Oslo, LL.D., F.R.S.Ed. (Pp. 1342+ix; illustrated. 40s.) Edinburgh and London: E. & S. Livingstone. 1966.

It is a measure of the popularity of this textbook that since the first edition in 1952 a new edition has been called for every two years. It represents the distillation of medicine as it is taught and thought by the Edinburgh school under the inspiration of Sir Stanley Davidson. Clearly, therefore, it fills a need felt not only in this country but in all the large number of countries where it is sold. It would be a tremendous achievement even to be able to cover the whole field of medicine in such a relatively small space and still retain the impression of literature as opposed to a tabulation of so-called facts. There is no doubt that for quick reference to the major points in the important diseases this book is excellent. It achieves this by taking the reader at a brisk trot through the major manifestations of disease mounted on short pithy sentences. It is to be hoped that a major reason for its popularity is not the lack of any controversial matter, nor any consideration of the weight of evidence for one view or the other, but a nasty suspicion remains that this may be so. If so, then the teachers of the students who follow this as their bible have much work to do, for while the Practice may be clear the Principles are not.

W. S. PEART.

Botulism

Botulism 1966. Symposium, Moscow, 1966. Edited by M. Ingram, M.A., Ph.D., and T. A. Roberts, B.Pharm., Ph.D. (Pp. 531+xii; illustrated. £6 6s.) London: Chapman & Hall. 1967.

Attendance at this symposium was limited to those "actively working" on its subject, and participants numbered only 55. This must have ensured well-informed discussions, but they are not reported. The papers are evidently in condensed form, but adequately illustrated, and include numerous tables and extensive reference lists. Twenty-four are by workers in the United States, 10 from the United Kingdom, 8 from the Soviet Union, 4 from Canada, and 1 or 2 each from six other countries. They deal first with the distribution of *Clostridium botulinum* in nature, particularly type E, which is almost always responsible when the food causing botulism is imperfectly preserved fish. It is reassuring to read in a paper from the Torry Research Station, Aberdeen, that though this organism is common in dredgings from the sea bottom off Norway it is apparently non-existent on our side of the North Sea. A further and longer series of papers deals with conditions affecting survival of the spores, their growth, and toxin production in foodstuffs. The toxins themselves, their chemistry, antigenicity, and pathological effects, botulism in animals, and laboratory methods, particularly for the isolation of *Cl. botulinum*, are the main subjects of the remaining papers. Included in the last-named are two papers, both by workers in England, on the fluorescent antibody technique for the recognition of the organism.

Botulism is a terrifying disease, and the toxins causing it are of course by far the most powerful poisons known. It strikes brutally in unexpected places, as at Loch Maree in 1923. There is little of the romance or horror of botulism in these rather dry pages. Indeed human outbreaks are mentioned only in the first and last papers. One records that all outbreaks in the Soviet Union since 1959 have been due to home-canned or home-pickled foods (fish, ham, or vegetables). The other reports an incident in Canada, fortunately controlled by recalling all tins of a product which had been under-processed owing to a misunderstanding, no allowance having been made for heat penetration according to the volume of the can contents.

Some interesting points emerge: it seems, for instance, that smoked salmon is an inimical medium for the growth of *Cl. botulinum* because the smoke contains phenols and, surprisingly, formaldehyde. Another author presents evidence that in the human disease toxin continues to be formed in the bowel as well as absorbed from it, and he therefore advocates administration of antitoxin by duodenal tube and high enema as well as intramuscularly. It may be news to most people that large numbers of ducks and gulls die of the disease.

Everyone directly interested in this subject must naturally possess this book. It is evidently because such people are few that the price is high, particularly for a volume reproduced by photolithography from typescript.

L. P. GARROD.

Rod and Serpent

The Rod and Serpent of Asklepios. Symbol of Medicine. By J. Schouten. (Pp. 260 +ix; illustrated. 65s.) London: Elsevier. 1967.

The snake-entwined staff, an example of which adorns the cover of the *B.M.J.*, is today universally recognized as the symbol of medicine and healing. But why the staff, and what is the significance of the snake? Dr. Schouten, a Dutch historian of art, gives the full and absorbing story in this beautifully produced and scholarly book.

The god of healing of the ancient Greeks was Asklepios, also known to the Romans as Aesculapius, who was depicted holding a staff around which a snake was coiled. Both are thought to have represented healing, and this heathen symbolism, having survived the Christian Middle Ages, came to be used with increasing commonness to signify medicine and pharmacy, especially in herbals and pharmacopoeias, examples of which Dr. Schouten lists and illustrates. It was more popular in the Northern Reformation countries than in the parts of Europe where the Catholic patron saints of medicine, Cosmas and Damian, predominated.

Since the sixteenth century the staff encircled by two snakes, the Caduceus of Hermes-Mercury, has at times replaced the Asklepian symbol as the emblem of medicine, though it was not used as such in antiquity. It has the same allegorical significance of healing, one of the best-known uses being in the insignia of the U.S. Army Medical Department.

This is an important work which illustrates the contribution which can be made by the non-medical scholar to the history of medicine. No one without Dr. Schouten's knowledge of art history and of the background influences of mythology, religion, and allegory could have tackled this complex topic, and his book will become the standard reference work on it. Perhaps not many doctors will care to follow Dr. Schouten through all his carefully annotated data, but on the other hand anyone who wonders why his profession is symbolized by the rod-and-serpent will wish to consult this book, even if only to read the summary and to admire the excellent illustrations.

EDWIN CLARKE.

Books Received

Review is not precluded by notice here of books recently received.

The Young Offender. By Dr. D. J. West. (Pp. 333. 35s.) London: Gerald Duckworth. 1967.

Student Health Services in Great Britain and Northern Ireland. By Professor Alex Mair. (Pp. 236+xii. 42s.) Oxford: Pergamon. 1967.

Atlas of Stereotaxic Anatomy of the Telencephalon. Anatomo-Radiological Studies. By J. Talairach and G. Szikla. (Pp. 326+xix; illustrated. 260 F.) Paris: Masson. 1967.

Parkinson's Disease. By Leslie Oliver, M.B., B.S., F.R.C.S., F.A.C.S. (Pp. 69; illustrated. 21s.) London: William Heinemann. 1967.

Insulin-Kohlenhydratstoffwechsel und Nervale Regulation. Verhandlungen der Deutschen Gesellschaft für Experimentelle Medizin. Vol. 15. Edited by Professor K. Lohmann. Pp. 247; illustrated. £1 17s. 10d.) Jena: Volk und Gesundheit. 1966.

Pathology in Britain in the First Half of the Twentieth Century, with a Glance Forward*

C. H. BROWNING,† M.D., F.C.PATH., F.R.S.

Brit. med. J., 1967, 3, 359–362

I appreciate greatly the opportunity to commemorate my friend E. H. Kettle. Not only was he a distinguished pathologist, too early taken from us, but his wide culture, shining humanity, and rich sense of humour inspired deep affection and respect in all who had the good fortune to know him. We were contemporaries and our active lives in pathology began with this century. In Britain it was an exciting period, since only recently had the subject ceased to be a mere servant of the clinicians. The pioneers of the change were the generation immediately our seniors. Thus beginners like Kettle and myself found circumstances that were new. The current roll of our Pathological Society shows that under 3% were pathologists in 1924, therefore I shall try to picture affairs during the first half of the century, so that you may appreciate how the present state has evolved. Training, practice, teaching, and research will be touched on. If I draw largely on personal experiences, that is because they are the most vivid. But my conditions were not unusual, except perhaps that the men who influenced me were of quite phenomenal calibre. In the light of what I have learned I shall offer some opinions which may be shared but are not borrowed.

Scope and Status of Pathology—How it Became a Career

Pathologists had come to belong practically to two classes, hospital and academic. A good physician's interest in his patient after death was to find out whether the postmortem findings had been correctly predicted. In a word, the hospital pathologist was his ancillary. This routine verification of well-known facts was essential for teaching the natural history of disease, but not much to the benefit of future victims. Of course, there were the occasional curiosities. Surgeons, however, thanks to Lister, now dared to inspect deep lesions during life and supply fresh human tissues for examination. Thus, reporting on operation specimens was a considerable duty. A hospital pathologist's appointment, unlike the clinicians', did not promise lucrative private practice, there being small demand. A few university professorships of pathology existed ; but the chance of reaching such a position was remote. These academic pathologists in their departments were isolated from patients in hospital, where at that time the obvious problems lay.

In Glasgow Joseph Coats, besides engaging in clinical work, had been pathologist to a large general hospital and teacher of pathology for about 25 years. Finally he became full-time professor, and soon effected a revolution by securing at the Western Infirmary an Institute where teaching and hospital work were carried on jointly. On its inauguration in 1896 he stated: "Our circumstances here are, I think I may say, unique, and I think I may add that they are in a sense ideal. . . . There is thus combined under one roof and under one superintendence both the Infirmary and the University Pathological Departments. . . . My pathological friends tell me that such a conjunction of interest is a happy ideal which is nowhere else realized" (see Browning, 1952). Glasgow's example, however, was only tardily followed elsewhere.

Running a combined department was relatively simple at the beginning. Apart from teaching, the chief occupation was with the hospital's morbid anatomy and histology (including blood examinations). Histological methods were similar to today's, but fewer and simpler—present histochemical methods are an example of the change. The preservation of natural colours in naked-eye museum preparations had begun, but the treasures on the shelves were in spirit. I remember concluding that time could be spent better than by visiting there. Chemical pathology was represented chiefly by simple side-room tests. Medical microbiology and parasitology consisted mainly of examining pus for organisms, throat swabs for diphtheria bacilli, sputum and urine for tubercle bacilli, intestinal contents for the typhoid bacillus, dysenteric amoebae, or worms, and blood for malarial parasites or microfilariae. Serology consisted of a micro form of Widal test. Animals were occasionally inoculated for detection of tuberculosis, also for plague which visited Glasgow at that time. Blood cultures were rarely asked for. Research in pathology was generally taken to mean the description of unusual cases ; the experimental method was reintroduced to us in 1899 by Coats's successor, Robert Muir, with his investigation on leucocytosis. The most striking later advances have been the wider understanding of chemical pathology, the growth of bacteriology (including immunology and virology) stimulated especially by the war of 1914–18, haematology, and genetics. Increased interest in the living patient and the active development of the experimental approach have been of vital importance. It is scarcely possible to exaggerate the debt of human pathology to the scientific study of protracted model diseases induced in animals. Various names are given to different aspects of this discipline ; but since all centre on altered function and structure, they are pathology.

After Coats's innovation there arose the problem of training a body of young pathologists for future needs. Pathology had always attracted keen men ; for a few years they acted as junior teachers or hospital pathologists, but then shifted to the clinical side. Earlier still there were the famous physicians and surgeons whose names live in the diseases they identified. One of the later examples was a young surgeon, John Bland-Sutton, who made outstanding contributions on the pathology of the ovaries and Fallopian tubes. When a clinical panjandrum asked where such things were seen, the reply was, "In the public mortuary." A friend who apparently did not relish necropsies had provided this opportunity. The tradition of pathologist–

† Professor Emeritus of Bacteriology, University of Glasgow.

physician lingered and "when I was a pathologist" was a familiar expression in London. There were some who could afford to continue their hobby of pathology through possessing private resources—for example, "marrying a nursing-home" or practising vaccine therapy when that became fashionable. Others again were just infatuated with pathology and felt that things must eventually turn out all right; possibly national temperament explained this faith, for at the first meeting of the Pathological Society William Osler remarked that the language of the Society was Scots.

Coats at the opening of his Institute said: "I cannot think of a better way of advancing the scientific position of our school and at the same time conferring great benefits on the community than by some man who is able, conferring a moderate endowment on those who may devote themselves to research." He did not live to see this hope realized, but a Coats memorial scholarship was established in 1899. Growing appreciation of the value of medical research led to foundations and grants by private and public bodies. Personally, I must thank chiefly the Carnegie Trust, the M.R.C., and I.C.I. for support. Various circumstances have increased the demand for pathologists until the number now far exceeds the most sanguine hopes of 1900. Dible's (1957) history of the Pathological Society tells of the devoted men who won recognition for their subject as an independent scientific discipline. A similar magnification of the pathologist's status has occurred in other spheres, and all these changes have accelerated (see Ledingham, 1925). No longer kennelled in the dead-house, the pathologist is now important clinically and in general social esteem. Let us hope that he will not be forced to go abroad in order to find conditions congenial for research, nor be frustrated officially in his effort to serve individual patients.

Training

As a student starting with a term of morbid histology, both the subject and my teachers, Robert Muir and A. R. Ferguson, greatly attracted me and, being encouraged, I haunted their department. At the time a local epidemic of smallpox broke out and Ferguson was studying the behaviour of the leucocytes and the histopathology of the skin. My interest was aroused and, anxious to do some work, I asked Professor Muir for a subject; he proposed the development of the granular leucocytes in the human foetus. When the results came into print I had graduated in medicine and, the Coats scholarship being open, I applied. There was no other candidate, and after a practical examination I became the first holder; the tenure was a year. Professor Muir asked me to take part in his work on haemolytic sera. He interpreted the scholar's duties in a most enlightened way by arranging that only part of the time was spent on research, thus leaving the rest at disposal for me to become familiar with the round of the Institute. I also attended a postgraduate laboratory course in medical bacteriology. My only "menial" duty was, in the first few months, to wash blood suspensions by turning a hand centrifuge until a small electric one was built. I read widely round the various subjects of the daily work and tutored several students—an admirable exercise for a future instructor.

Gaining a Carnegie fellowship and, on Muir's recommendation, accepted by Ehrlich as a voluntary worker, I went to Frankfurt late in 1905 and stayed till the autumn of 1907. At first I worked on haemolysis under the kindly eye of Hans Sachs; but soon Roehl, engaged on the biological side of trypanosomiasis chemotherapy, left and I replaced him. This was the greatest good luck, because during a year and a half I came into the centre of Ehrlich's chief interest. The Georg-Speyer-Haus for experimental chemotherapy was soon opened with both chemical and biological departments; so I made contact with the chemists. A landmark of that time was the arrival of Miss R. Gulbransen in the biological department. Afterwards, in 1916, I was able to invite her with support of the M.R.C. to share in research on the aminoacridine antiseptics; she came at once to Britain from her native Norway to further this work. Thus began a fortunate collaboration, which lasted some 20 years.

The personalities of both Ehrlich and Muir fascinated me. Muir was rather uncommunicative as a rule, from preoccupation mainly, and his intentions had to be divined; on formal occasions, however, he was magnificently clear. Ehrlich, never at rest, talked with telling vivacity and wit, yet nothing was unpremeditated. Both were highly concentrated men and did not relish interruptions. I recall vividly their occasional reactions. The laboratory which Muir used for haemolytic experiments was shared by a budding clinician doing a small bit of bacteriology. No doubt he hailed meetings with an influential figure like the professor as a useful opportunity to ripen acquaintanceship; so he made small talk. This was tolerated for a time, until one day on opening the door Muir saw the man and immediately, raising his arm prophet-wise, said emphatically, "X, I am busy this morning." Once on going to Ehrlich's room I found him arranging matters with a senior member of the institute; concluding, he said that they would continue next forenoon. The other replied that he was sorry, but he had a piano lesson at that time. Ehrlich courteously changed the hour and they parted; then eyeing me sternly he said, "You must have only one wife." I can think of no greater exhilaration for a young pathologist than the period with Ehrlich, though eventually, I fear, one would have burnt up in his fire, just as he consumed himself. With Muir I spent over 25 years; his fine critical mind, unbreakable integrity, generosity in allowing pupils to follow their own bent, and high appreciation of life both mental and material made a lasting imprint (Ehrlich, see Muir 1915-6; Browning, 1954, 1955; Muir, see Cappell, 1961).

These first four graduate years—including six months as house-physician—were a sort of informal apprenticeship quite free from the burden of impending examinations or other routine. They were the most memorable and valuable part of my scientific education. Nowadays, I fancy, it will be almost impossible to reach a senior position without an extra degree in science; however, I doubt whether such training is superior to my less formal course. But if the extra degree is necessary meanwhile, I should recommend the bare minimum of written examinations. These may serve in the words of Robbie Burns as the fear of hell that holds the wretch in order; but I am sure that such trials ultimately sap independence of mind. For the beginner, time spent in research, especially jointly with an experienced investigator, is invaluable and enjoyable. It shows how difficulties arise and the ways in which they are tackled. Sound initiative, usually a slowly maturing faculty, is fostered. There is a dilemma—how much to read? The immense cargo of knowledge piling up everywhere today may eventually hinder advance; repeatedly I have met sharp young people who decided from reading that what can be has been done, so why further effort. It appeals to me as a most enlightened provision of this College that Membership may be gained by published original work. I hope this approach will be freely encouraged.

Practice and Teaching

I was offered a university assistantship by Professor Muir soon after my return from Frankfurt. Personal selection of staff worked well in his hands to judge by the performance of the long line of his young people. At first I shared the general teaching and hospital work, later becoming responsible successively for bacteriology and clinical pathology. In 1911-12 the professor's official medical staff consisted of three, with several part-time demonstrators for the practical classes. When I was appointed first director of the Bland-Sutton Institute at the Middlesex Hospital duties were similar, except that I secured

Ernest Kennaway to undertake chemical pathology. In time the irresolvable uncertainties of histopathology disillusioned me; it is an essential subordinate, but can be a deceitful master and may lead its devotees into devious courses—for example, fixing all of a specimen where tuberculosis might be suspected.

On returning to Glasgow in 1919 to the new chair of bacteriology, I fortunately was housed in the Pathological Institute. At Muir's suggestion pathology and bacteriology lectures were closely dovetailed. For instance, as soon as the other aspects of pyogenic diseases were dealt with, their bacteriology was taken up. I am convinced that such integration is the best way of dealing with the pathology of infections for medical students. They require a basic understanding of the science without the detail suited to specialists. I quote as the highest compliment words of Sir Robert Muir (1950): "Many teachers of the present day would benefit if they knew both what bacteriology was and how much Browning thought it necessary to teach the ordinary medical student. If they cut their courses accordingly, I think it would be of great importance in the medical curriculum." As to the form of teaching, since knowledge is best acquired through as many sensory paths as possible, specimens and lantern demonstrations accompanied each lecture. However, tutorials and demonstrations should familiarize students with the main points of a subject before they attend formal lectures by a senior teacher; these can then be a perspective with emphasis on outstanding features. Unfortunately the order is usually reversed and one has to talk systematically to an audience both ignorant of the vocabulary and incapable of taking useful notes. Practical courses in pathology should contribute to training in manual dexterity. Medical men require skill in using their hands; and opportunities to acquire this are indispensable. The teaching which was mutually most rewarding took place in small practical classes and discussions with graduates engaged in research. When a junior turned his results into words for publication an important duty was to ensure that he made himself intelligible. I always found lucid, accurate expression on paper difficult; and few others seem less hampered. I chose knowledgeable young people to read my own MSS. When they queried any point, an acceptable alteration was devised. Obviously, if the reader had difficulty in grasping what was intended, the writer had failed and it was best to try again. Often I have asked the author of an unintelligible jumble, "Tell me what you wish to say," and at once he would give a brief and clear statement. However, I do not suggest composition by direct dictation. It is essential to write a draft, read it, make changes, rearrange words, paragraphs, etc., and then get a typed copy, which will show up further imperfections. I have known half a dozen redrafts to be required.

Examining never gave me satisfaction. Excellence in written papers is certainly no guarantee that a candidate will be good at his profession, but only means that he has a faculty commonly associated with general capacity. I have greater confidence in "practicals" and "vivas," which represent conditions much more akin to situations in real life. However, there are many young people who prefer written tests. This, I fancy, depends much on two factors—one is the elasticity of the inexperienced mind, which can accommodate a whole science for several days and disgorge chunks on demand; the other is shyness, which recoils from a possibly unsympathetic human confrontation. Not all examiners possess the tact of Kettle—once when about to interview a Scottish student, he asked, "Who are you?" and the answer was "Fine, thank you"; whereupon Kettle paused, looked at his list again and said, "Very good; now what is your name?" If there were sufficient teachers I would accept their opinion that a candidate should pass. In case of an adverse judgement an independent examination would be available as a sort of court of criminal appeal. I entirely agree with a statement of Robert Muir that good performance in examinations serves chiefly to bring to the notice of their seniors students who lack financial backing.

Research

While in the inanimate world spectacular triumphs of accomplishment abound—for example, in engineering—it is humiliating that we still signally fail to cope with more than a few of the biological derangements which afflict man and other animals. Research, actively pursued, is imperative. A medically trained pathologist who does not feel that adventure in his domain is a large part of the salt of life has surely mistaken his vocation. But the way has been difficult. As we saw, this century found the pathology departments of universities and hospitals mainly separate. Hospital authorities generally viewed research in pathology, particularly of the experimental kind, as at best a luxury. There is now much improvement, but even yet facilities for research could be more accessible; all who show aptitude (which is not yet measurable by the usual examinations) should possess the opportunities. The idea of separating research sheep from routine goats, with no common field, is frustrating. To be convinced of this one has only to watch the personality of an individual who, in addition to answering the calls of others, is also making progress with an investigation, preferably of his own choice. There is, too, the mass benefit conferred on his fellows. Of course, this implies no criticism of fine research institutions—for example, the Lister, a private organization, or the National Institute. As to "team-work," this can be highly effective only when it is a free association of individuals possessing various mental or physical skills, who jointly face an intricate problem.

Valuable results could be obtained even recently with moderate material outlays apart from the essential element of time. But now expenses grow ever greater; where are the means to be got? Calls in the name of specified diseases used to be very successful. But benefactors cannot be guaranteed any sure return; the only promises are past successes. Another important consideration is that investigation may be hampered by too precise terms of a gift. Cancer, coronary thrombosis, poliomyelitis are all dreaded and appealing words. But the best prospects of ameliorating such maladies and of general progress in the mastery of disease probably lie in research under less restricted designations—for example, growth, degeneration, viruses. As Ehrlich aptly put it, research is like a voyage in a balloon; one never knows in advance what the scenery will be on landing, but it is essential to be prepared to appreciate its features. It is clear that the number of people able to play Maecenas has of late drastically diminished. Their successors are committees, boards, or trusts, all multiple impersonalities whose judgements will be governed by presumed responsibility to others, compromise, and so on. Collectively they are likely to lack the faculty of making the bold wise decision open to one person disposing of his own. In any case, nobody but the researcher himself should decide what road he will follow, and he must be trusted. That does not mean that his judgements will always be right. Nevertheless, at least a proportion of research should be financed privately. If there are no longer large givers, there might well be many moderate ones responsive to appeals honestly advanced.

How does the investigator get his ideas—probably in various ways, sometimes unknown to himself. Certain minds seize fruitful analogies which are unguessed by most. For Medicine, particularly, a classic instance is Lister's inspiration that the agents of sepsis in wounds, like those of Pasteur's fermentation and putrefaction, must be micro-organisms. On the whole, however, there is not much explicit information as to why experimenters have acted as they did. In my experience, which conforms with general belief, new concrete facts are usually discovered by the scientific exploration of observations made under novel conditions. Such conditions may arise spontaneously or be produced experimentally; they need not be created on the basis of a theory. It must be added, however, that extraneous circumstances often play a large part in determining the importance attributed to any particular discovery.

Prospects

Extension of the field has been phenomenal and yet so many unsolved problems remain that one cannot but be hopeful of further progress. Most encouraging is the knowledge of what Nature unassisted occasionally brings about. It is foolish to guess what will be the next discoveries; there have been too many fatuous prophecies. After all, *Penicillium notatum* was wafted on to the culture of one who had spent much effort to demonstrate the impossibility of effecting locally what penicillin afterwards accomplished systemically. Again, to promulgate that cancer is an inevitable genetic vice seems a gambler's throw when metastases may develop after 20 years of latency following surgical removal of a primary; and still more astonishing is spontaneous regression of malignant tumours in man. Pathology is a science and art dependent on tools provided by chemistry and physics. It is now obvious that physical pathology will be actively fostered like its chemical twin. On one thing, however, I feel sure—so long as we remain human beings we shall never fathom the whole intricacy of disease processes. But we can expect to multiply powers of modifying these processes at decisive points, so as to prevent, compensate for, or even reverse derangements which interfere with healthy functioning.

I would pose several questions with another bearing. Even recently, medical pathologists were competent technicians, free to advance their subject by new methods and observations. Is this to be suppressed by administrative demands or replaced by computers? Again, what about the respective responsibilities of those medically qualified and the others who lack this background? Can the latter be reliable advisers in many problems concerning patients? On medical education in general my only comment is strong approval of the view that a nominally "all-in" qualification is an anachronism. It should be replaced by a primary qualification requiring a less detailed but broader pupillary curriculum, and this would be followed in a proportion of cases by preparation for a special qualification. Further, it is only common sense that a candidate's primary qualification should normally be gained at about age 25 and thereafter he be entitled to earn as well as learn. Means must be found, however, to prevent the cruel waste involved in rejecting candidates at the later stages of primary training.

To end, I recognize that pathology has now reached a diversity and a complexity which prevent more pathologists of my sort from emerging. The conditions of Membership of the College are clear evidence for this. At the same time I cannot but regret that an existence so varied and enjoyable should become impossible.

CONFERENCES AND MEETINGS

Disorders of Protein Metabolism: Conference at R.C.P. London

[FROM A SPECIAL CORRESPONDENT]

A conference on recent advances in plasma-protein disturbances and proteinuria was held at the Royal College of Physicians of London on 7 and 8 July.

Professor SHEILA SHERLOCK (Royal Free Hospital, London) was chairman of the first session, at which Dr. T. FREEMAN (National Institute for Medical Research, London) outlined the functions of certain plasma proteins. He pointed out that Laurell electrophoresis had now made possible both the quantitative and qualitative assessment of plasma-protein fractions, and that nearly 50 different types, several of them still unnamed, had been demonstrated, though the functions of most of them were not yet understood. Dr. Freeman divided the plasma proteins of known function into two categories—"suicidal" proteins, which were broken down in performing their task, and biophilic proteins, which were used repeatedly. Chain reactions employing suicidal proteins might be a safety device resembling a combination lock, the proteins being destroyed because their actions, in some cases at least, were potentially dangerous. Complement and the formation of fibrin from fibrinogen were examples of this.

Though albumin comprised the largest fraction of the plasma proteins and had been studied most, its function was still poorly understood. In the past albumin had been thought of as a reserve pool of amino-acids, but at least two other functions were more likely possibilities. Firstly, albumin provided a non-specific transport mechanism for many substances, including bile acids, metals, drugs, and excesses of vitamins and hormones. Secondly, in common with the other plasma proteins, albumin maintained the colloid osmotic pressure of the blood. Nevertheless, high albumin levels were not essential for the latter because patients with the rare condition of analbuminaemia generally remained remarkably well. Dr. Freeman went on to describe the functions of two other plasma proteins which were better understood. The substance transferrin bound iron atoms and carried them to the reticulocytes, and it also appeared to have some antibacterial action. Haptoglobins of several types combined with haemoglobin, and probably acted as scavengers. He thought that it was likely that all plasma proteins had specific functions, and that new techniques would lead to great advances during the next ten years.

Liver Disease

Discussing the influence of liver disease on plasma-protein levels, Dr. V. M. ROSENOER (Royal Free Hospital) divided the plasma proteins into two main groups—the immunoglobulins, synthesized extrahepatically, and the remainder, synthesized wholly or mainly in the liver. A high proportion of patients with liver conditions had increased immunoglobulin levels, but these were not disease-specific and therefore had no use in differential diagnosis, neither did their presence imply the existence of an autoimmune process in the liver. Similarly, the fall in blood levels of plasma proteins formed in the liver had been found to bear no direct relation to individual hepatic diseases. Nevertheless, it had been possible to develop methods for the direct study of plasma-protein synthesis rates in the liver by the use of radioactive tracers. Surprisingly, these studies had produced no evidence of a feedback mechanism by which the serum albumin concentration could influence the rate of albumin synthesis.

Dr. Rosenoer concluded by emphasizing the importance of an adequate supply of amino-acids for protein synthesis, and suggested that protein intake should not be unduly restricted in patients with liver disease; nor, on the other hand, was it useful to give excessive quantities of protein. Normal dietary levels were usually best.

Dr. G. NEALE (Royal Postgraduate Medical School, London) instanced some diseases associated with hypoproteinaemia, pointing out that low levels of albumin and other plasma proteins were caused either by reduced production (in liver diseases and malnutrition of the kwashiorkor type), by increased catabolism in acute illness, or by direct loss from the body. The last took place through the skin after burns, from the kidneys in the nephrotic syndrome, and from the gut in protein-losing enteropathy. Protein loss from the gut occurred at various levels: from the stomach in carcinoma and hypertrophic gastritis; from the small bowel in regional ileitis, idiopathic steatorrhoea, tropical sprue, and after irradiation; and from the colon in carcinoma and ulcerative colitis.

Dr. Neale emphasized that severe hypoproteinaemia could produce a clinical picture closely resembling kwashiorkor, the effects of inadequate dietary intake being mimicked by malabsorption or maldigestion. Thus two clinical types of hypoproteinaemia could be distinguished: firstly protein loss causing caloric undernutrition, and secondly inadequate adsorption leading to the kwashiorkor type. Intravenous albumin had proved valuable in treatment of the latter. In the subsequent discussion Dr. Neale said that corticosteroids were not often successful in the treatment of patients with protein-losing enteropathy.

Impaired Immunity

The first part of the afternoon session, under the chairmanship of Professor C. E. DENT, F.R.S. (University College Hospital, London), was devoted to hypogammaglobulinaemia. Dr. J. R. DAVIS (Institute of Child Health, London) described the normal course of immunoglobulin levels during intra-uterine life and in the newborn. Maternal gammaglobulin-G crossed the placenta in late pregnancy, giving protection to the baby after birth until the latter's own gammaglobulin-G production took over. In premature babies, on the other hand, maternal gammaglobulin-G levels fell before the infant's own production was sufficient to give protection against infection. Thus premature babies often lacked immunity at about the time of their discharge from hospital, just when they were first exposed to infection. Dr. Davis suggested that this situation predisposed to overwhelming infection and cot death, and he proposed a large-scale trial of the administration of gammaglobulin to premature babies.

Turning to hypogammaglobulinaemia in children, Dr. J. F. SOOTHILL (Institute of Child Health) said that antibody deficiency was only one aspect of impaired immunity. Both antibody and cellular immunity could be either qualitatively or quantitatively deficient or both. Hypogammaglobulinaemia in children was a quantitative antibody deficiency, commoner in boys, which could be a temporary, self-correcting phase; a familial tendency; the result of congenital rubella; or due to some unknown cause. Children with hypogammaglobulinaemia were particularly susceptible to coccal infections, whereas those with a deficiency in cellular immunity had an impaired resistance to virus infections. Several measures could be employed in the management of children deficient in antibodies. Chemotherapy for individual attacks (or prophylactically), gammaglobulin injections, and immunization were all useful, though live virus vaccines were potentially dangerous in these children and best avoided. *Pneumocystis carinii* infections, the commonest cause of death among boys with hypogammaglobulinaemia, could now be successfully treated with pentamidine.

Dr. K. M. CITRON (Brompton Hospital, London) described hypogammaglobulinaemia in adults, classifying this as either primary or secondary, the latter having several possible causes, including the toxic effect of drugs and neoplasia. The sex incidence of the primary type was about equal among adult patients, who often had histories of multiple infection. Though the adult form always had its onset in adult life, there was some evidence of a familial pattern, and it might be precipitated by the influence of exogenous factors on genetically predisposed individuals. Cellular immunity was normally intact.

Paraproteins and Malignancy

The second part of the afternoon session was devoted to paraproteins, and Dr. J. R. HOBBS (Royal Postgraduate Medical School) described the clinical aspects of paraprotein production. In contrast to the wide range of antibodies produced in response to antigens, paraproteins were almost always of a single immunoglobulin type in each affected person, and were derived from abnormal cell clones. These were associated with malignant conditions—myelomatosis, lymphoma, and leukaemia—in about three-quarters of those affected, but appeared to run a benign course or resolve spontaneously in the remaining quarter. Though the abnormal immunoglobulins (paraproteins) of myelomatosis were of several types, two paraproteins were found in the same patient in about 2% of cases. All the abnormal immunoglobulins were immunologically deficient, and the excretion of large quantities of their light chains in some patients with myelomatosis could be detected as Bence Jones protein in the urine.

Concluding, Dr. Hobbs emphasized the progressive increase of abnormal immunoglobulin levels in all malignant paraproteinaemias, and he deduced from the rate of progression that a single abnormal cell might take 40 years to proliferate to the point at which a paraproteinaemia became clinically apparent. Patients known to have paraproteins in their blood should be retested annually in case the condition was progressive.

Discussing the treatment of the paraproteinaemias, Dr. D. A. G. GALTON (Chester Beatty Research Institute, London) gave some provisional results of a Medical Research Council trial which had shown that melphalan and cyclophosphamide were about equally effective in the treatment of myelomatosis. The response to treatment had been found to be very slow in some patients, and it was important to persist even if the initial response seemed disappointing. Nevertheless, the possible improvement obtainable by chemotherapy had to be carefully weighed against the toxic effects of the agents at prevent available.

The first day's proceedings concluded with the Lilly Lecture on "Antibodies without Antigenic Stimulation," in which Professor J. G. WALDENSTRÖM (University of Lund, Sweden) surveyed the field of paraprotein disease with special reference to myelomatosis.

Lipoprotein Disorders

Lipoprotein disorders were the subject of the paper by Dr. JUNE K. LLOYD (Institute of Child Health) given at the final session of the conference, with Dr. J. C. HAWKSLEY (University College Hospital) in the chair. After outlining methods for identification of lipoproteins by paper electrophoresis and ultracentrifuge separation, Dr. Lloyd described the primary disorders of lipoprotein metabolism due to genetic defects. Lipoproteins were deficient in a-betalipoproteinaemia and Tangier disease (alphalipoprotein deficiency), both conditions being inherited as autosomal recessives. The first of these was characterized by acanthocytosis of the red blood cells, steatorrhoea, pigmentary retinopathy, and ataxic neuropathy, while patients with Tangier disease had cholesterol deposits visible in the tonsils and causing lymph-node enlargement and hepatosplenomegaly.

By contrast, lipoprotein levels were raised in the other inherited conditions described by Dr. Lloyd. Elevation of triglyceride, also inherited as an autosomal recessive, was fat-induced in essential hypertriglyceridaemia (idiopathic hyperlipaemia) and brought on by carbohydrates in the carbohydrate-induced hypertriglyceridaemias. These conditions were treated by restriction of fats and carbohydrates respectively, and medium-chain triglycerides could usefully be added to the low-fat diets. Familial hypercholesterolaemia (hyperbetalipoproteinaemia) was an autosomal dominant condition seen in both homozygous and heterozygous forms, of which the latter was more common. Very high blood-cholesterol levels, especially in the homozygous form, were associated with coronary artery disease having its onset in childhood, adolescence, or early adult life. Satisfactory management was difficult—again particularly so in homozygous patients—but polyunsaturated-fat (such as corn oil) diets and cholesterol-lowering drugs had been found to produce some reduction in blood-cholesterol levels.

Massive Proteinuria

The conference concluded with two papers devoted to proteinuria, in the first of which Dr. J. D. BLAINEY (United Birmingham Hospitals) described a study of massive proteinuria, defined as loss of more than 10 g. of protein per 24-hour period in adults. This loss took place from the glomeruli, and oedema and low serum-albumin levels were found consistently in such patients, who suffered from nephritis of various types (but not from pyelonephritis, which seldom caused massive proteinuria). A total of 430 patients had been subjected to detailed investigation, including renal biopsy and protein studies on the serum and urine. Treatment consisted of continuous corticosteroid therapy in minimal effective dosage; a high-protein, high-calorie diet; and prophylactic oral penicillin. In addition, a salt-free diet was given while patients had oedema, and hypotensive drugs were used if the diastolic pressure exceeded 100 mm. Hg.

In the final paper, Dr. H. S. PLATT (University College Hospital) discussed the causes of tubular proteinuria, which produced much smaller losses of proteins of lower molecular weight than those found in the massive glomerular proteinuria of the nephrotic syndrome. Tubular proteinuria could be due to any one of a number of causes, including chronic cadmium poisoning, the Fanconi syndrome, and galactosaemia. It was also found mixed with glomerular proteinuria in Wilson's disease, phenacetin nephropathy, chronic pyelonephritis, and other conditions.

Centenary Annual Meeting of Canadian Medical Association

[FROM A SPECIAL CORRESPONDENT]

The Canadian Medical Association celebrated its centenary by holding the 1967 Annual Meeting in Quebec City, the place of its founding in the year of Canadian Confederation, and in Montreal. As part of this meeting scientific sessions were held at the Château Frontenac Hotel, in Quebec. A report of some of these sessions is given below.

Triple-X Female

Dr. MURRAY BARR (London, Ontario) opened the scientific meeting with a discussion on the trisomy of chromosomes, with particular reference to that of the X chromosome. Dr. Barr—who during the course of the meeting was presented with the F. N. G. Starr Award by the Canadian Medical Association, as recognition of his contributions to the field of genetics—outlined the various genetic abnormalities that at present were identified with chromosomal non-disjunction. The latter was an error of mitosis, in which two similar chromosomes (instead of the usual one) were contributed to the daughter cell during germ cell maturation. This might occur with any of the 22 pairs of autosomes or with the sex chromosome.

Dr. Barr reminded his audience that each chromosome contained hundreds of genes, the number varying with the length of the chromosome. The deoxyribonucleic-acid-containing genes elaborated ribonucleic acid, both of a specific nature for each gene locus, and the ribonucleic acid in turn guided the production of specific cytoplasmic enzymes. When trisomy existed, each gene locus was present three times instead of twice, and consequently enzymes under control of the trisomic chromosome would theoretically be produced at 50% above their normal values. Enzymatic imbalances occurred and interfered with normal embryonic development. Dr. Barr observed that the longer the chromosome the greater the expected damage would be, and the details of the abnormalities produced would vary depending on which chromosome was trisomic.

When chromosomes were arranged as a conventional karyotype, the 44 autosomes could be divided into seven groups, A to G, on the basis of morphological similarity. Trisomy of autosomes in all seven groups was found in spontaneously aborted foetuses, while numerical chromosome abnormalities accounted for at least 20% of embryonic loss. Trisomy of autosomes was usually lethal during the first trimester, and with rare exceptions only three types of autosomal trisomy allowed the foetus to proceed to live birth—namely, trisomy 15, trisomy 18, and trisomy 21 (which caused mongolism or Langdon Down's syndrome).

Dr. Barr pointed out that, though the X chromosome was large, X chromosome trisomy did not result in death or in the production of serious physical defects as would be expected. The X chromosomes were about the same length as autosome 6, with a large number of gene loci, only a few of which were concerned directly with sex differentiation. Trisomy of the X chromosome did not interfere more drastically with the normal development of various systems and organs because of the phenomenon of X chromosome heteropyknosis—where one of the chromosomes of the female was tightly coiled, compact, and adherent to the inner surface of the nuclear membrane. This chromosome was relatively genetically inactive and ensured that there was not a great predominance of active genetic material from the female. Moreover, the X chromosome of paternal origin could take this inactive heteropyknotic role also, and the form of the X chromosome, paternal or maternal, was decided at the moment when the embryo underwent implantation.

This ability to form inactive X chromosomes gave the subject a protective mechanism not afforded in cases of autosomal trisomy, and gave a reasonable basis for explaining the lesser degrees of malformation found in triple-X trisomy. Dr. Barr presented accounts of six patients with X trisomy and noted that, though a clear clinical syndrome had not been established, certain features might be found in some cases—including club foot, subluxation of the elbow, flexion deformities of the fingers and other skeletal abnormalities, webbed fingers, hydrocephalus, spastic quadriplegia, optic atrophy, cataract, and corneal opacities. Nevertheless, triple X females were usually physically normal, but they ran a greater risk than average of some sort of defect, with no consistent pattern.

Concluding, Dr. Barr suggested that the incidence of X trisomy was 1 in 850 female babies, and noted that until mass chromosome analyses were done on all newborns chromosome abnormalities of this type would go undetected, lacking as they did a well-defined clinical picture.

Calcium Homoeostasis

Discussing the regulation of body calcium, Dr. D. H. COPP (Vancouver) emphasized that, though the body of a 60-kg. man contained over 1 kg. of calcium, less than 0.1% of this was extracellular and involved in important functions such as muscular contraction, neuromuscular excitability, membrane permeability, and enzyme activity.

Using sequential high calcium and low calcium perfusions of the parathyroid gland, Dr. Copp and his associates had observed a very rapid fall in plasma calcium during the high calcium perfusions, and the expected rise with low calcium perfusions—this presumably due to endogenous parathyroid hormone. Following the final perfusion, the test animals had had the thyroid and parathyroid glands removed. Instead of the expected fall in plasma calcium a marked and sustained rise had occurred, and it was suggested that the fall in calcium during high calcium perfusions was not due to suppressed parathyroid hormone production but to a humoral agent which actively lowered blood calcium. Hence they had concluded that a previously unrecognized hormone was involved. This was now accepted as calcitonin or thyrocalcitonin, derived from the " light cells " or " C " cells, which made up 2–4% of the mammalian thyroid.

Calcitonin was a straight-chain polypeptide, as was parathyroid hormone, but it was about one-half the size and lacked three amino-acids found in parathyroid hormone: isoleucine, trytophane, and cysteine. It was antigenic, with definite species differences, and was effective in man in doses of less than 0.1 mg.

Calcitonin had been found to be effective after nephrectomy and total evisceration, so that its action was not through either kidney or intestine. It was also effective in the parathyroidectomized animal, so that it was more than an inhibitor of parathyroid action. Experimental evidence suggested that, while parathyroid hormone increased osteolysis, calcitonin inhibited normal osteolysis, the osteolytic effect of parathyroid hormone, and also the osteolysis induced by vitamin A. Active remodelling of bone, stimulated by parathyroid hormone, was inhibited by calcitonin, with a reduction in the number of osteoclasts.

The control of serum calcium levels had two facets: firstly a fine control mechanism, and secondly a relatively crude control, which operated in the thyroparathyroidectomized animal. The former was the parathyroid-hormone–calcitonin system, in which each hormone could act independently of the other, and where the hormone output was controlled by the concentration of calcium ions in the blood. The latter depended on such factors as the labile calcium store in bone, the availability of calcium from the gut (favoured by the presence of vitamin D), the excretion of calcium, and the effect of calcium and phosphate in blood on the deposition of new bone mineral.

Dr. Copp emphasized that the clinical value of calcitonin had not been established. The great hope was that it might have a beneficial effect in cases of osteoporosis, but, discouragingly, calcitonin had been found to act much more effectively in the young animal in inhibiting osteolysis.

Gastrointestinal Polyps

Reviewing current concepts about polyps of the gastrointestinal tract, Dr. WALTER MACKENZIE (University of Alberta, Edmonton) decried the tendency for the terms polyp and adenoma to be used interchangeably, and stated that this lack of precision, which was particularly noticeable in recent articles, had led to improper treatment.

In the diagnosis of benign tumour of the oesophagus, Dr. MacKenzie stressed the importance of careful *x*-ray examination, which revealed a smooth filling defect with normal mucosa overlying the tumour mass. He felt that gastric polyps were precarcinogenic, and he referred to a 12-year study of 20 patients with multiple gastric polyps, when three had developed proved malignancy. The use of gastroscopy had been invaluable in diagnosis, and could give an early indication of malignancy. Partial gastrectomy was the treatment of choice for multiple polyps, since this avoided the increased mortality and morbidity associated with total gastrectomy, and also the serious nutritional problems associated with the latter procedure.

The use of transillumination of the bowel in a dark-adapted operating-room was a useful procedure in visualizing small bowel tumours. The radiological examination of the small bowel was, Dr. MacKenzie stated, only as effective as the degree of awareness of the clinician and the degree of care taken by the radiologist.

In the colon a papillary or villous adenoma was potentially more dangerous than an adenomatous polyp, with an associated malignancy rate of 30–40 per cent. The relation of the adenomatous polyp to carcinoma remained one of the most controversial areas in the field of general surgery, though Dr. MacKenzie felt strongly that a significant positive correlation existed, pointing out that the frequency of carcinoma rose proportionately with the presence of multiple polyps. He supported the view that polyps might be the " flags " which signalled a carcinogenic stimulus. In congenital multiple polyposis of the colon possibly the carcinoma might be merely a manifestation of the large number of polyps and their potential to become malignant.

In the case of rectal polyps, it was generally agreed that removal of those within reach of the sigmoidoscope was indicated and was relatively simple. For those above this level he recommended colotomy and polypectomy for those which were clinically benign, and resection of the involved portion of the bowel for those which were not. He felt that the incidence of existing malignancy was greater with increased polyp size, but could see little justification for attempting to establish a so-called " critical " polyp size.

Industrial Rehabilitation

Mr. LAWRENCE PLEWES (Dunstable, Great Britain) outlined the services in the field of industrial rehabilitation available in England under the Disabled Persons Act. He pointed out that both the Ministry of Health and the Ministry of Labour were actively involved in this area, their activities being co-ordinated by a National Advisory Committee, composed of doctors, trade unionists, employers, and officials from both Ministries. At the local level there was the Disablement Advisory Committee with a similar composition, concentrating its efforts on local employment situations and individual disability problems.

Mr. Plewes felt strongly that traditional occupational therapy should be confined to diversional schemes for bed-ridden patients, and had no place in a modern rehabilitation service. All forms of passive physical therapy —such as heat, massage, diathermy, and ultrasonics—should be and had been replaced by exercises and machines and games. This change from the passive to the active form of therapy had not been easy, since it was difficult to persuade a patient, in a push-button age, that the best results would follow his own muscle contractions.

The usual pattern at a district general hospital was for limited rehabilitation services to cope with urgent short-stay patients. Regional centres with accommodation for in-patients catered for the more serious and long-term problems. The rehabilitation centre, such as the one at Luton, used a factory milieu to both mobilize and evaluate the recovery of the patient. Simple machines, which employed a conditioned reflex on the part of the operator, were generally used, and enabled the patient to do useful work, avoiding the boredom of simple exercise, and in addition fostering a feeling of accomplishment. Noise was purposefully present in a moderate degree, allowing for a gradual adjustment back to a noisy environment while the patient was under sedation. This was important in post head-injury cases, where sudden exposure to noise could be intolerable. Dr. Plewes stressed that this industrial method was used no matter what type of employment the patient had previously held, and it had been found effective.

In those patients who were unable to return to normal employment sheltered workshop accommodation should be available. Once a patient had progressed to a point satisfactory from the medical aspect, he could be either returned to his normal occupation or referred to the industrial rehabilitation unit. At the latter the disabled person was evaluated by a highly skilled staff, and was then given a trial at several different appropriate occupations or sent to a private industrial concern for highly specialized rehabilitation courses. In all cases rehabilitation was on industrial lines. The pace was graded, and vocational assessment was a continuing feature. If further training was necessary the patient was sent to a Government training centre or technical college.

Dr. Plewes felt that the involvement of trade unionists in these programmes was most important for their success. He estimated that a community of 230,000 should have an industrial rehabilitation centre for 50 persons at the hospital, another 50 places in local industry, and a sheltered workshop for 50 disabled persons, plus an additional 100 places for the mentally disabled, to meet adequately the demand for service.

Growth Hormone Deficiencies in Childhood

Professor DOUGLAS HUBBLE (Birmingham, Great Britain) delivered the Tisdall Lecture (established in memory of Dr. Frederick Tisdall, a great Canadian paediatrician and nutritionist), on defective growth in childhood. Detailing his experience with a group of twenty-one cases of growth hormon deficiency, he classified this into idiopathic, genetic, and secondary. Thirteen of his cases fell into the first category, and included perinatal injury. Two cases were classified as genetic, which would be either autosomal recessive or non-sexed linked. Under secondary causes Professor Hubble included cases of craniopharyngioma, chromophobe adenomas, healed tubercular meningitis, and trauma.

Only seven cases were isolated growth hormone deficiencies ; eleven cases also had thyroid-stimulating-hormone deficiency, as shown by low serum protein-bound iodine levels. Professor Hubble felt that in some cases there was some failure of the thyroid gland dependent on the growth hormone deficiency, though attempts to verify this hypothesis had been unsuccessful. Corticotrophin deficiency occurred in four of his patients. The clinical picture of patients with growth hormone deficiency was apparent immaturity, normal intelligence, truncal obesity, retarded skeletal maturation, marked growth retardation, and, in many cases, episodes of spontaneous hypoglycaemia. All the patients over 15 years of age had shown retardation of puberty.

A combination of the radioimmunoassay and the intravenous insulin-tolerance test had been used for diagnosis, in conjunction with the human growth hormone nitrogen-retention test. Although these involved considerable technical difficulties, these tests had enabled the diagnosis of growth hormone deficiency to be made with precision, and for it to be excluded in other cases.

In children with growth hormone deficiency the treatment was with growth hormone derived from human pituitaries, since preparations of animal growth hormone gave no response. The dosage varied from 6 mg. weekly to 18 mg. weekly, and produced a greatly accelerated velocity of growth in the first year of treatment. This initial spurt was called the " catch-up " period. Normal growth rates could be achieved by prolonged therapy, but the " catch-up " growth period by no means allowed the leeway which had occurred in the early years to be made up. Most of the 40 cm. of rapid growth in the first three years of life was irrecoverable. If hypothyroidism was present, thyroxine should be given concurrently, for the two hormones appeared to act synergistically, though thyroxine could not replace growth hormone.

RESEARCH IN PROGRESS

M.R.C. Annual Report

At the end of March 1967 the Medical Research Council's own establishments consisted of the National Institute for Medical Research and 77 research units, including four overseas. The Council's report,[1] which was published on 27 July, states that individual members of the Council's external scientific staff continued to be attached to other institutions, and that the Council supported 46 research groups.

At a total of £11,885,000 the Parliamentary grants-in-aid represented an increase, at constant prices, of 13.4% over the previous year, and the report points out that in the past few years there has been a rate of increase of between 10 and 13%. In the same period the increase in the recurrent costs of the Council's own establishments has been about 6%, at constant prices, owing, the report says, to new building projects, "sophistication" in staffing and equipment, and an increased number of new investigations.

The Council also received £1,016,039 from other sources, enabling it to spend a total of £12,800,000 during the period. Nevertheless, the report points out that, because of existing commitments, only £900,000 of this was "freely deployable" within the year, and it comments that this latter sum is of particular significance in forward planning if the Council is to encourage new lines of research.

Expenditure on research grants now accounts for over 17% of the Council's total budget, compared with 10% or less up to five years ago; in the year 1966–7 a total of £2,210,000 was spent in this way. The report also states that the Council provided 24 travelling fellowships, 224 scholarships for training and further education, and 157 awards for intercalated courses.

Revised Charter

The report also records the fact that the revised Charter of the M.R.C. received the Queen's assent on 26 October 1966. The M.R.C.'s first Charter was granted in 1920, and, though the new Charter does not alter the constitutional position, it will enable the number of members to be raised from 12 to a maximum of 16. All members of the M.R.C. are now appointed by the Secretary of State for Education and Science, the Chairman and Deputy Chairman after consultation with the Council and the scientific members with the Council and the President of the Royal Society.

Discussing the M.R.C.'s policy on computers, the report says that the Council's Computer Advisory Committee has advised the M.R.C. that its computer unit in London, which was established at the beginning of this year, will be able to serve the needs of all staff locally and some of them elsewhere. The Council's policy is that as much work as possible should be done on large computers providing a general service, and that smaller machines should be provided for local use only if there are special indications.

Record Linkage

With regard to a proposed national system of record linkage, the report says that the Council's Committee on General Epidemiology believes that this could be created on existing practices. The basis of the suggested scheme would be birth, marriage, and death records, together with selected data of long-term interest from hospital inpatient records. Besides enabling long-term studies on, for example, people exposed to occupational hazards, such a scheme would aid studies in genetics, of screening programmes, and of the delayed toxic effects of drugs. Though the Council recognizes that, besides requiring changes in the law and administrative procedures, the project would be costly to introduce, it believes that "the advantages of such a scheme are so manifold as to outweigh the difficulties of its implementation."

Work is in progress on Phase I and Phase II of the New Clinical Research Centre at Northwich Park, which will include, respectively, part of the Research Institute and some hospital beds, and the main operating theatre block and the maternity department (see *B.M.J.*, 1966, **1**, 535).

It is planned to have a multidisciplinary approach at the Centre, with interchange of workers between the various scientific fields, and it is hoped that roughly half the scientific staff will be clinical and half non-clinical workers.

Medical Education

The Council's evidence and advice to the Royal Commission on Medical Education are also mentioned in the report. These include, firstly, the suggestion that universities should be encouraged to make their entry requirements as broad as possible, and in particular that mathematics should be an alternative to one of the subjects required for entry to the preclinical course. Secondly, the Council recommended that both the duration and the context of the preclinical course should be as flexible as possible, and that the range of intercalated courses should be widened to include biological and paraclinical studies other than the traditional subjects. Thirdly, since the length of the present clinical course might lessen the prospects of an individual's success in original work, consideration should be given to introducing a short clinical course, designed to introduce him to the problems and opportunities rather than towards training for practice. Finally, the Council proposed that optional subjects concerned with research methods might be introduced into courses designed for training specialists.

New Committees

Besides mentioning that six committees have been disbanded, the report also records that the following new ones have been established or reconstituted (names of chairmen in parentheses): *Research in Industrial and Applied Psychology* (Professor Sir Austin Bradford Hill, F.R.S.); *Dental* (Professor B. Cohen); and *Non-ionizing Radiations* (Professor A. R. Currie). Three new working parties have also been set up: on *Anti-human Lymphocyte Serum* (Professor M. F. A. Woodruff); on *The Use of Anti-D Gamma Globulin for the Prevention of Iso-immunization of Rh-negative Women During Pregnancy* (Professor P. L. Mollison); and on the *Treatment of Myocardial Infarction* (Professor W. Melville Arnott).

As well as summaries of the work of the Council's own research establishments and of other projects supported by it, the report contains a series of articles on selected aspects of medical research. The subjects of the latter are: studies on the human Y chromosome; ageing; the control of protein synthesis in living cells; experimental studies on viral carcinogenesis; progress towards the control of leprosy; some problems in the control of virus vaccines; pulmonary hypersensitivity disease due to organic dusts; recent research on thrombosis; some aspects of the organization of visual pathways; and some observations on the age of reaching puberty.

Letters to the Editor should not exceed 500 words.

Snakebite Poisoning

SIR,—A newspaper recently reported[1] that a man was bitten by a snake which he subsequently brought to hospital. The report alleges that doctors could not identify the snake and were thus unable to decide if antivenom should be given. The snake was therefore taken to a zoo, while back at the hospital "... doctors were waiting for the vital identification."

Distinction of poisonous from non-poisonous snakes is often difficult, but is *not* important for the clinician—his function should be to diagnose whether poisoning has or has not occurred, and, if so, of what severity. In Britain the only naturally occurring poisonous snake is a viper, and thus there is no need to distinguish between viper-bite poisoning and envenoming from elapid bites (a problem in some tropical countries). The assumption that poisonous snake bite is the same as snakebite poisoning is wrong; it has greatly confused the medical treatment of snakebite. In at least half the victims bitten by poisonous snakes no venom is injected; this half can be immediately recognized in hospitals because there is no swelling (local swelling starts within minutes of an adder bite if venom has been injected). Antivenom should not be given to such patients.

It is my belief and practice that antivenom should be given only to the minority of snakebite victims (about one-quarter) showing clinical evidence of *systemic* envenoming as well as local effects of poisoning. In systemic viper-bite poisoning, the common early signs are vomiting and blood-stained spit (the victim should cough hard to produce this spit). An hour or so later blood becomes non-clotting. More details on the medical treatment of snakebite have been recorded previously in your columns.[2]—I am, etc.,

H. ALISTAIR REID.

Undesirable Effects of Marijuana

SIR,—The use of marijuana (cannabis), usually in the form of cigarettes, is widespread. Its undesirable effects, alone or combined with other drugs, are not fully known. Accounts of four young men referred to me over the past six months may therefore be of interest.

(1) An undergraduate of 19 smoked "reefers" at parties about a dozen times without ill effects. He relaxed and was able to appreciate music, companionship, and conversation more keenly. He then smoked "an extra large one and something exploded inside him." He felt intense anxiety and a frightening sense of unreality. That night he was given a hypnotic. Four months later, in spite of psychiatric treatment, he still experiences severe anxiety and unreality, and has frightening hypnagogic hallucinations.

There are no psychotic features. He is an obsessional young man, trying to resolve neurotic problems of adolescence. The effect of the drug has been to precipitate an acute anxiety state.

(2) An art student of 19 experimented with lysergic acid diethylamide (L.S.D.) over a period of several months without obvious ill effect. At a party he took 100 mg. L.S.D. by mouth and smoked two "reefers." He felt "depersonalized, about to disintegrate, and go mad." He became extremely anxious. He was treated with trifluoperazine 2 mg. three times a day and chlordiazepoxide 10 mg. three times a day for a fortnight, and symptoms subsided. A week later he again smoked a "reefer." Anxiety immediately returned and he experienced fleeting visual hallucinations. These subsided slowly with treatment over several weeks.

After full recovery he was resolved not to smoke marijuana again.

(3) A man of 24 was admitted to hospital, having drilled a hole into, but not through, his skull. He had done this with a dental foot-drill, under the influence of marijuana. He gave a clear account of himself. After obtaining an honours degree in law he drifted in and out of several jobs. On coming down from Cambridge he came under the influence of a group of people who believe that, after a suitable period of preparation with L.S.D. and marijuana, trepanning of the skull, by releasing cerebral pressure, will enable an individual to conquer time.

Although he showed no overt psychotic signs, other than what amounted to a delusional belief in this idea, his history suggested schizophrenia simplex. He refused psychiatric treatment.

(4) This patient, aged 24, began to smoke marijuana after leaving art school, without apparent ill effect. Two years ago he became involved with the same group of people mentioned in Case 3. Under their influence he took L.S.D and marijuana. At the beginning of this year he became frightened and felt that he had been chosen as a guinea-pig for a trepanning experiment. Psychotic symptoms developed and spread. He was treated by psychoanalytic methods for several months without relief of psychotic symptoms. During this time he continued to smoke marijuana in spite of the fact that this seemed to increase the intensity of his symptoms. Eventually he was admitted to a nursing-home and treated with phenothiazine drugs.

He appeared to be an "inadequate personality," the psychotic state having been brought about by L.S.D. and marijuana.—I am, etc.,

Disturbed Geriatric Patients

SIR,—Dr. R. C. Greenberg's resolution at the Annual Representative Meeting (*Supplement*, 22 July, p. 91) deploring the lack of facilities for the care of disturbed geriatric patients did not in my view go far enough. There is, I think, an urgent need for the medical and other requirements of the aged to be rationalized. At the present time the services provided by the local authorities are usually subdivided into two parts—one ruled by the medical officer of health dealing with the domiciliary services, health visiting, home nursing, chiropody, etc., the other by the chief welfare officer and his separate staffs running the local authority welfare homes.

From the point of view of the family doctor, and in an emergency the medical officer of health, difficulties arise in assessing whether an old person requires a bed in an old people's home, a geriatric hospital, or a mental hospital. The beds in each are controlled by different people and more often than not the liaison between these people is less than it might be. Not only are patients sometimes sent to unsuitable accommodation in the first place, but transfers from one type of bed to another are far from the simple administrative manœuvres that one would expect them to be.

Somehow, and as a matter of urgency, the facilities available for the old people must be integrated, or at least co-ordinated, if the best uses of the available resources are to be made. The suggestion that a senior doctor, from either the hospital or the local authority service, should be responsible for this co-ordination is long overdue.—I am, etc.,

H. M. DAVIES,
Assistant County Medical Officer.

Newton Abbot,
Devon.

Hetacillin and Ampicillin

SIR,—A recent article entitled "Laboratory and Pharmacological Studies in Man with Hetacillin and Ampicillin" (24 June, p. 804) presents data obtained by Beecham researchers utilizing ampicillin (Beecham) and hetacillin (Bristol). The hetacillin used in these studies was partly prepared by Beecham and partly acquired in the market.

The absorption and excretion results cited in this paper are at variance with those reported by independent investigators in this country.[1 2] Indeed, the variation in the data obtained by the Beecham investigators themselves (Study A vs. B and C vs. D) might have prompted their enlisting the aid of independent observers, particularly when, surprisingly enough, their ampicillin levels are much higher and their hetacillin levels much lower than those found by independent investigators.[1 2]

The authors conclude by stating "that hetacillin would be expected to possess inferior therapeutic efficacy compared with ampicillin." To date, in well-conducted clinical trials on file with the Food and Drug Administration, over 3,000 patients have been treated, with results which refute this statement. Infections caused by both Gram-positive and Gram-negative micro-organisms have responded to hetacillin in the same or lower dosages than those recommended for ampicillin. Details of these clinical studies will appear in print shortly.—I am, etc.,

R. E. WEISSGERBER,
Vice President—Scientific Director,
Bristol Laboratories International
Corporation.

Treatment of Mendelson's Syndrome

SIR,—I read with interest the report of a case of Mendelson's syndrome treated with tracheostomy and hydrocortisone (17 June, p. 745). This article indicates yet once again the considerable dangers associated with obstetric general anaesthesia. Pulmonary complications secondary to aspiration of gastric contents before, during, and after obstetric anaesthesia remain an important cause of morbidity and mortality.[1] However, these are largely preventable and treatable. The initial improvement in the patient described by Dr. R. M. Nicholl and his colleagues following intravenous hydrocortisone and oxygen under pressure illustrates the basis of the treatment in Mendelson's syndrome.[2 3] The endotracheal tube was removed prematurely before the pulmonary oedema had been alleviated, and as a result respiratory distress and hypoxia persisted.

Endotracheal intubation (preferably nasal) should have been performed again and continuous intermittent positive pressure ventilation with warmed humidified gases and tracheobronchial toilet instituted. This is an excellent method of reducing dead space in the short-term case. With controlled or assisted ventilation, the pulmonary symptoms and hypoxia exhibited by this patient would have been remarkably improved within hours. The decision to perform a tracheostomy could then have been delayed in the expectation of a rapid improvement in the patient's condition. The drugs used during anaesthesia were not described and could have had a bearing on the management of the case. Arterial blood-gas studies should have been performed (if equipment was available) to determine the oxygen tension and the acid-base status of the patient.

The prevention and treatment of Mendelson's syndrome should be along the following lines:

(1) Recognition that all obstetric patients in labour who are to have general anaesthesia must be regarded as having a full stomach irrespective of the last oral intake of food or drink.[4 5]

(2) Prior to anaesthesia, oral premedication with antacids will reduce the gastric acidity, and therefore the incidence of Mendelson's syndrome will be diminished.[4 6]

(3) Should pulmonary aspiration occur, clearance of the airways is essential. Endotracheal intubation (preferably nasal) should be performed followed by deep suction if respiratory distress ensues.[2 3] Tracheal-bronchial lavage is not advised as dissemination of the acid occurs.[7]

(4) Intermittent positive pressure ventilation with 100% oxygen should be instituted[2 3] and premature removal of the endotracheal tube should be avoided.

(5) Generous hydrocortisone administration, both intravenously and intramuscularly, should be given.[5 8 9]

(6) Bronchodilator drugs may be used to alleviate bronchospasm.[3 5]

(7) Antibiotic coverage is essential in any case of pulmonary aspiration.[10]

(8) Determination of the *p*H of the gastric contents is necessary to estimate the severity of the pulmonary complications. When the *p*H of the aspirated fluid is 2.5 or under, Mendelson's syndrome is likely to occur.[4] The *p*H of the aspirated fluid suctioned from the trachea will give a falsely high value as the bronchial mucosa attempts to neutralize the acid rapidly, by the outpouring of oedema fluid.

Vomiting and regurgitation of stomach contents in the obstetric patient should be regarded as preventable. If pulmonary complications do occur as a result of either of these incidents, rapid and vigorous treatment must be instituted.—I am, etc.,

What is Psychosomatic Disease?

SIR,—The article by Dr. F. Feldman and others (1 July, p. 14) and your leading article (1 July, p. 1) both raise the general question of the use of the term "psychosomatic disease." If it is merely thought that one factor among many in the aetiology of a disease is sometimes emotional disturbance, it seems a plain misuse of words to describe the disease simply as psychosomatic. This term can be justified only if a disease is invariably —in the words of your leading article—"an illness in which the organic lesions are the consequence of emotional disturbances."

Dermatitis artefacta can properly be called psychosomatic. So, in a special sense, can alcoholic cirrhosis of the liver and even obesity. But none of the diseases which are often alleged to be "psychosomatic," such as colitis, asthma, and duodenal ulcer, warrant that description. Attacks of asthma can surely be precipitated by respiratory infections, by non-specific irritants such as smog, by allergens, or by emotional upsets. The only possible justification, therefore, for claiming that asthma is psychosomatic is that the defect in the bronchioles in asthmatic individuals is itself caused by emotional disturbance. This view can be reached only by faith, not by observation and reason. No doubt in some subjects of duodenal ulcer there is a relationship between the emotional state and the attacks. But attacks often have no discoverable cause. Feldman and others have done a valuable service by revealing the unsatisfactory nature of many of the papers which have purported to demonstrate that ulcerative colitis is psychosomatic.

Even if it were true that psychological factors are all-important in ulcerative colitis this would not justify the belief of the "some physicians" of your leading article who "regard psychotherapy as the mainstay of treatment." The only reason for reaching that conclusion is the existence of objective evidence that psychotherapy is beneficial. Deducing that a remedy must be effective because it follows from a theory of aetiology is one of the great errors made by our profession over the centuries. Trephining the skull (to release the demon), bleeding, starving, purging, eradicating septic foci, and pleating the stomach were all thus justified. —I am, etc.,

Farnham, Surrey. JOHN W. TODD.

Fulminating Ulcerative Colitis

SIR,—Your leading article (22 July, p. 188) rightly draws attention to the importance of an early resort to surgery in fulminating ulcerative colitis. The often lethal complication of colonic perforation is the most important reason for the striking difference in mortality figures when results of emergency surgery and planned surgery in ulcerative colitis are compared. To say, therefore, that surgery is "kept in reserve for failed medical treatment or when there is perforation . . ." is capable of misinterpretation; we need to recognize the pre-perforation state and operate at this earlier time.

The risk of perforation determines not only the timing of surgery but also the type of operation done. The danger in only raising an ileostomy (because the patient is gravely ill) is that the disease is left in situ and perforation can still occur. The best operation, even in the seriously ill patient, is one that removes the colon; the standard subtotal colectomy with ileostomy is the procedure of choice, therefore, even under these conditions. This policy is well borne out by the excellent paper by Professor J. C. Goligher and his colleagues in the same issue (p. 193). —I am, etc.,

T. A. BOXALL.

Abdominal Decompression and Foetal Blood Gases

SIR,—In foetuses at increased hazard of death during labour foetal heart rate monitoring and foetal blood collection are used routinely in our hospital. The value and safety of these procedures have been established.[1-3] In many of the foetuses studied where clinical evidence of foetal distress (meconium in the liquor or abnormal foetal heart rate) was present both the subsequent foetal heart rate record and the foetal blood measurements were normal. This routine use of foetal diagnostic methods in the presence of clinical foetal distress presented us with the opportunity of testing the hypothesis that abdominal decompression improves oxygenation of the foetus.[4]

An Emerson Birtheez abdominal decompression suit was used applying a negative pressure of 70–110 mm. Hg. The first five patients were decompressed using the intermittent technique of 15 seconds on, 15 seconds off, for 10 to 35 minutes; the next nine had continuous decompression maintained for 10 to 20 minutes.

Thirteen patients were in the first stage of labour and one was at full dilatation; foetal heart rate was monitored in nine[5] and intra-amniotic pressure in five. All had clinical evidence of foetal distress. Foetal scalp capillary blood[2] was collected before and during abdominal decompression, and in seven of the 14 patients a further specimen was taken five to 45 minutes after stopping decompression. Foetal blood *p*H, Pco_2, and Po_2 were measured in an I.L. 113 Sl ultramicro electrode assembly. (Table I.)

Abdominal decompression did not significantly alter Po_2, *p*H, or Pco_2 (see Table II).

The mean Po_3 change was smaller than the 99% confidence limits of the Po_2 measurements, ±1.2 mm. Hg.[6] Resting amniotic pressure fell during decompression by a mean of 14 mm. Hg (7, 12, 13, 14, and 25 mm. Hg). The foetal heart rate pattern did not change during the experiments—this included two cases with slowing of 20 to 30 beats/min. during contractions. Labour pain was diminished, but several patients complained of discomfort when decompression above 70 mm. Hg was attempted.

Case No. 3 deserves special comment because of the presence of foetal acidosis and hypercapnia. The mother's capillary blood *p*H was normal at 7.43. Abdominal decompression for 35 minutes did not result in any improvement in foetal *p*H, Po_2, or Pco_2. Foetal heart rate recorded after the decompression was normal. The baby was delivered by vacuum extraction and had an Apgar score of six at two minutes. The cord was twice around the neck at delivery. This was the probable cause of the foetal acidosis, and acidosis due to cord compression may not respond to decompression. On the other hand, placental insufficiency due to pre-eclampsia may respond to repeated decompression, as Blecher's results[7] suggest.

This study was stopped after 14 investigations were completed, as it was clear that abdominal decompression produced no increase in foetal scalp blood Po_2. Even if a very large series showed a small but significant increase of foetal blood Po_2 one would not know whether decompression increased general foetal oxygenation or merely improved venous drainage from the scalp. Venous return from the scalp may be improved during decompression by slight elevation of the foetal head and by increasing the venous-pressure difference between the foetal great veins and scalp veins. If such a change occurred it could raise the scalp-capillary blood Po_2 several mm. Hg.

Heyns often uses higher pressures for decompression than those used in the present study (60–150 mm. Hg compared with 60–110 mm. Hg). Also the design of his decompression suit is different from that of the Emerson unit. Apart from these limitations of the present investigations, no evidence was found that during one period of abdominal decompression foetal oxygenation was improved. Of course, the effect of repeated abdominal decompression during the last two months of pregnancy might be different. A reliable way of increasing foetal blood Po_2 is for the mother to breathe 100% oxygen by the CIG polymask or anaesthetic face mask.[6]—We are, etc.,

Lyell's Toxic Epidermal Necrolysis

SIR,—The aetiology of toxic epidermal necrolysis (Lyell's disease, scalded-skin syndrome) is unknown but several agents have been implicated. In adults there often is a close association with drug ingestion, whereas in children bacterial infection seems to be relevant. Dr. J. Jefferson (24 June, p. 802) has demonstrated a high incidence of *Staphylococcus aureus*, especially phage type 71, among his 31 cases occurring in infants and children, and has suggested that the primary skin lesion could be caused by a toxin elaborated by this organism. Other authors also have observed this association.[1] Furthermore, Ritter's disease of neonates, which closely resembles Lyell's disease, has yielded a high incidence of the staphylococcus of phage types 3B/71[2] or 55/71.[3] The relationship of these Group 2 bacteria to the lesions of Lyell's disease was recently the subject of a short editorial.[4]

With such observations in mind I have reviewed the clinical records of four typical cases of histologically confirmed Lyell's disease. Cases 1 and 2, which proved fatal, have been previously reported.[5] Subsequently Cases 3 and 4 have been successfully treated at the Royal Perth Hospital.

All were elderly females. There was no instance of a clearly defined relationship between ingestion of drugs and the onset of the skin syndrome. Shortly after admission Case 1 manifested a urinary infection from which *Staphylococcus aureus* was cultured in significant numbers. At necropsy in Case 2 a lung abscess caused by *Staphylococcus aureus* was revealed. Histologically the wall of this abscess was undergoing organization and therefore was probably developing at the time of onset of the skin disease some 10 days previously. The skin lesions, which in both the above patients had been treated before admission to this hospital, were sterile. Sections of skin taken at necropsy, however, showed numerous organisms, including clumped Gram-positive cocci. In the third and fourth patients, who recovered after five and nine weeks respectively, skin swabs taken on admission grew abundant *Staphylococcus aureus.*

Further studies concerning grouping and phage-typing of these organisms were not undertaken. Nevertheless, the incidence of the suggested pathogen in all four patients may be of some significance. It points to a possible common denominator in the disease of infants, children, and adults and suggests that the presence of *Staphylococcus aureus* should be sought, in future, when the diagnosis of toxic epidermal necrolysis is made.—I am, etc.,

KEITH B. SHILKIN.

Warning of Massive Pulmonary Embolism

SIR,—The paper by Dr. M. A. Barraclough and Mr. M. V. Braimbridge (28 January, p. 217) of a successful surgical removal of a massive embolism in a nurse, and the subsequent letter by Dr. J. S. Short (20 May, p. 510), underline several important points. I heartily endorse Dr. Short's statement that an early diagnosis at the time of the usual "warning embolus" is not difficult, but often wanting. Pulmonary embolism, with or without infarction, is a common and potentially fatal disease. In addition to the commonly recognized associations, such as bed rest, obesity, and pregnancy, it can occur in apparently healthy young adults.[1, 2]

There are many excellent papers, leading articles,[3] and letters[4] on the subject, but patients undoubtedly still die because of misdiagnosis and failure to institute immediate anticoagulant therapy. Surgical removal of massive pulmonary emboli, thrombectomy, and partial vena cava obliteration should now be possible in most major general hospitals.[5, 6] Many of these patients need never reach the operating-theatre if a correct early diagnosis had been made in the patient with faintness, syncope, transient cerebral ischaemia ("vasospasm"), "unexplained" dyspnoea, "pleurisy," and "recurrent or unresolved" pneumonia. Such patients need not have any definite signs in arms, legs, or elsewhere.

The current controversy about the relation of venous thrombosis and oral contraceptives may, perhaps, help to raise the general index of suspicion.—I am, etc.,

W. G. SMITH.

"Swallowed" Endotracheal Tube

SIR,—In the medical memorandum by Mr. J. A. S. Dickson and Mr. G. C. Fraser (24 June, p. 811) "Swallowed Endotracheal Tube," and in the subsequent correspondence, one most important point has not been sufficiently emphasized. All the babies recovered despite the iatrogenic efforts to prevent resuscitation. This must mean that these neonates were not really in need of intermittent positive pressure respiration via an endotracheal tube, except possibly the case reported by Mr. M. G. Prinn (15 July, p. 176).

Your correspondents insist on the need for training of junior obstetric staff in endotracheal intubation. To me this seems to be putting the cart before the horse. These junior staff should first of all be taught the difference between the neonate who merely requires what might be called primitive but time-honoured methods of resuscitation plus a good deal of patience, and the infant in need of all the most sophisticated techniques available. In the latter case the young doctor should be able to call on specialized experienced help.

If junior medical staff are taught sophisticated techniques without also being given considerable practical tuition in selection of the correct type of case on which to use these techniques, then serious, possibly tragic, accidents will occur. This is an aphorism by no means confined to obstetric anaesthesia.

The nub of the problem lies in the last words of Dr. R. A. Binning's letter (8 July, p. 111) ". . . a neonate which is *really* in need of intubation"—the italics are mine.—I am, etc.,

Royal Hospital,
Chesterfield.

H. E. POOLER.

SIR,—I find myself in complete agreement with Dr. J. V. I. Young (22 July, p. 242) in his contention that the routine use of endotracheal intubation in the presence of neonatal asphyxia is wrong. The indiscriminate passage of an endotracheal tube, I believe, comes under the heading of "meddlesome midwifery."

In the absence of obstruction due to mucus, meconium, etc., the passage of an endotracheal tube, owing to its cross-section acting as a foreign body in the lumen of the trachea, actually impairs the airway instead of improving it. It would be interesting to know the result of a long-term follow-up done to show whether the damage done to the delicate mucous membrane of a baby's vocal cords persists into adult life.

Intubation in the presence of neonatal asphyxia should be performed only when the child fails to respond to oxygen given by face-mask and gentle pressure on the rebreathing bag.—I am, etc.,

London W.1.

MASSEY DAWKINS.

Intrauterine Contraceptive Devices

SIR,—Over 35,000 intrauterine devices have now been inserted at the 170 clinics of the Family Planning Association so far approved for this purpose. Usually the device has been a Lippes loop, but some Birnberg bows and Saf-T-Coils have been fitted.

Analysing a large international series, Tietze[1] reports that the Lippes loop escaped through the uterine wall in about 0.04% of cases—usually without any apparent harm to the patient. We have not yet heard of the uterus being perforated during or after insertion of an I.U.D. in one of our clinics, but this has almost certainly happened from time to time. We should be grateful if gynaecologists would let us know of any such cases that have come to their notice—or may do so in the future.—We are, etc.,

HILARY HILL,
Medical Secretary.

SARA R. ABELS,
Assistant Medical Secretary.

Family Planning Association,

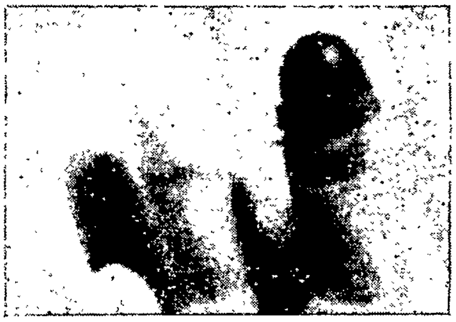
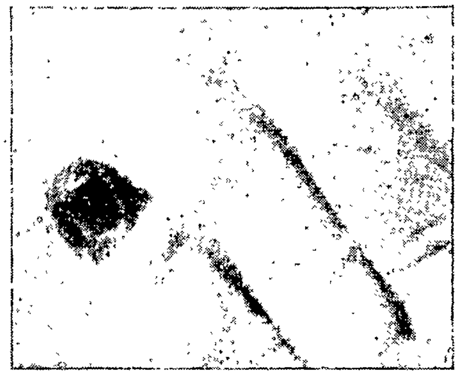
Hazard from Nylon

SIR,—The following case report illustrates the danger of using nylon fibre in babies' clothing.

A 7-day-old infant had mittens of knitted nylon fibre "wool." Some hours after these had been put on by her mother they were removed to reveal that a piece of nylon fibre from the inside of the mitten had formed a tight constricting band round the tip of the middle finger just distal to the terminal interphalangeal joint. The tip of the finger (see photographs) was black and obviously ischaemic.





A similar band had formed round the middle finger of the other hand, but fortunately had not produced ischaemia.

My thanks are due to Mr. R. L. Lewis, Consultant Surgeon, Haverfordwest, for his help and advice with the case.

—I am, etc.,

Haverfordwest,
Pembrokeshire.

G. G. NOOTT.

Nalidixic Acid and Intracranial Hypertension

SIR,—Following the report of Drs. L. O. Boréus and B. Sundström (17 June, p. 744), I should like to record another case of intracranial hypertension in a child during treatment with nalidixic acid.

A male infant, born with ectopia vesicae and epispadias, was admitted to hospital at 9 weeks of age for corrective surgery. At 7 months of age, eight weeks after his discharge from hospital, the infant was given nalidixic acid 250 mg. four times a day for a presumed urinary infection, as he seemed to have colic and had made a poor weight gain. Three days later the infant began to vomit his feeds and became irritable. The following day he continued to vomit, cried incessantly, and was noticed to have a bulging fontanelle. On admission to hospital the infant was considerably underweight, being only 11 lb. 3 oz. (5.1 kg.). The anterior fontanelle was tense and bulging, the scalp veins were prominent, but there was no neck stiffness and Kernig's sign was negative. The head circumference was 16½ in. (42.1 cm.) and the chest circumference was 16 in. (40.9 cm.). Although irritable and crying, the infant was afebrile and alert, there was no infection of the ears, nose, or throat, and the fundi and all other systems were normal except for the surgical procedures previously undertaken for the congenital abnormalities. In view of the raised intracranial pressure a subdural tap was performed and C.S.F. was obtained. It contained 1,600 R.B.C., 14 W.B.C., 4 polymorphonuclear leucocytes, 10 lymphocytes, glucose 50 mg., protein 30 mg., and was sterile on culture. Nalidixic acid therapy was immediately discontinued. Additional investigations showed a white blood count of 11,500 with 42% polymorphonuclear leucocytes and 58% lymphocytes, blood urea 41 mg./100 ml., serum sodium 148, chlorides 109, and potassium 4.9 mEq/l. A blood culture was sterile and the urine contained numerous pus cells and *Escherichia coli*. *X*-ray of skull showed slight separation of the sutures.

Following the "subdural" tapping the fontanelle was less tense, the baby became less irritable, and the vomiting ceased. Within four days the tension was normal and the infant had returned to a happy and contented state. Ampicillin 125 mg. six-hourly was given during this period for the urinary infection, but as the organism proved to be resistant to this drug nitrofurantoin 15 mg. six-hourly was substituted.

Seven days later, when the infant was feeding well and beginning to gain weight, a further course of nalidixic acid in the same dose, 250 mg. six-hourly, was given and within 48 hours there was definite increase in tension and bulging of the anterior fontanelle with prominence of the scalp veins. The following day the infant was irritable, and in view of the obviously raised pressure the drug was withdrawn; three days later the fontanelle tension had returned to normal. At this time his urine still contained *E. coli*, now insensitive to nitrofurantoin but sensitive to ampicillin, so this was substituted in dosage of 125 mg. six-hourly. During the next six weeks the infant fed well and gained 3½ lb. (1.6 kg.) in weight. He was therefore discharged home on a maintenance dosage of ampicillin 125 mg. 12-hourly and has remained well on follow-up.

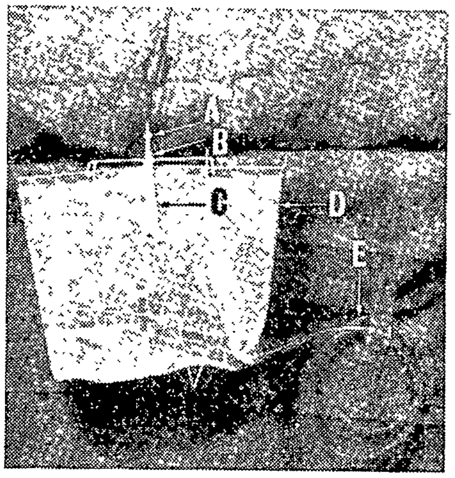
In the present case the dosage of nalidixic acid prescribed for the infant was twice the recommended one of 100 mg. per kg. body weight per day, and this was used in the second course to see if the condition could be reproduced. As headache and vomiting have been reported as side-effects of nalidixic acid therapy, the possibility of raised intracranial pressure should be considered if such symptoms are severe or prolonged. In view of the increasing use of nalidixic acid in infancy and childhood, this complication, especially if larger than normal dosage is used, should be appreciated, as a bulging fontanelle in the infant has serious implications and presents a difficult problem in differential diagnosis.—I am, etc.,

O. D. FISHER.

St. Bartholomew's Hospital,
Rochester, Kent.

Disposable Drainage Bag for Peritoneal Dialysis

SIR,—Drainage of the peritoneal cavity during dialysis poses the same problems in asepsis as closed drainage of the bladder, and standard urine collection bags are sometimes used for the purpose. The emptying of these bags every hour provides a useful opportunity to confirm that each cycle has drained adequately and to check fluid balance, but it involves at least 24 disconnexions of the drainage circuit per dialysis, with the inevitable risk of introducing infection. We have therefore adapted the Aldon urine collecting bag[1] to provide unbroken closed drainage while retaining the advantage of an hourly check on drainage and fluid balance.



The bag shown in the accompanying Figure is supplied sterile by Aldington Laboratories, Aldington Frith, Mersham, Ashford, Kent, at a price that makes it readily disposable. It incorporates the following features:

(A) Female Luer connector which accepts the Dialaflex peritoneal dialysis set (Allen and Hanburys) as illustrated.

(B) Short connecting tube. When this is cut aseptically below the Luer connector it will accept the Plexitron R 61 L peritoneal dialysis set (Baxter Laboratories).

(C) Non-return valve consisting of a length of soft plastic tubing. This is very effective in preventing reflux of fluid during emptying of the bag, but small air bubbles occasionally slip past it. It is therefore advisable to clamp the drainage arm of the peritoneal dialysis set just above the bag during emptying operations as an additional safeguard. Kinking of the plastic tube—which is easily seen and corrected without disconnexion of the bag—has obstructed drainage on one or two occasions.

(D) Bag of capacity about 3.2 l.—sufficient for a single drainage cycle even during dehydration with hypertonic fluids.

(E) Four foot (1.2 m.) drainage tube for emptying bag. This is closed by a spigot which can be discarded and replaced by a haemostat on the tube if preferred.

The bag is made of strong plastic which withstands repeated distension and emptying—in over 100 dialyses we have not encountered a "burst." It does not have the volume graduations found on urine collecting bags, since these graduations are not sufficiently accurate for fluid balance during peritoneal dialysis and they become more inaccurate after the bag has been refilled several times. The volume can be measured accurately in a 4 l. polypropylene measuring cylinder. If it is essential to avoid spilling peritoneal fluid (e.g., if the patient has hepatitis) the long drainage tube (E) can be connected to a stoppered 20 l. jerrycan mounted on a patient-weighing scale.—We are, etc.,

Fenfluramine

SIR,—I was very interested to read the account in "Today's Drugs" of our product fenfluramine (Ponderax) (15 July, p. 159). I would, however, like to bring to your attention two points on dosage and cost.

We recommend an adult dose of two tablets a day. In refractory obesity[1] the dosage employed was four tablets a day, and this higher dosage explained why there was a higher incidence of side-effects than normal. We regard this flexibility of dosage as being very important in the management of obesity.

As from 1 May 1967 the basic N.H.S. cost of 100 tablets was 35s., and there is of course considerable saving on packs of 500 and 1,000 tablets.—I am, etc.,

A. BOIS,
Managing Director.

Screening for Cervical Cancer

SIR,—In your leading article (24 June, p. 782) it was suggested that the results of routine cervical screening have been disappointing, on the basis of a report that the incidence of invasive carcinoma of the cervix has remained virtually unchanged,[1] in spite of the detection of large numbers of pre-invasive lesions. But it has been the general experience that many unsuspected cases of early invasive carcinoma, as well as carcinoma-in-situ, are brought to light by a screening programme, so the incidence of invasive carcinoma may be expected to remain virtually unchanged, or even to rise at first.

In the comprehensive survey in British Columbia[2] the incidence of invasive carcinoma per 100,000 females was 3.4 and 3.5 in those who had had previous cervical smears, and 32.3 and 24.1 in those who had not been included in the screening programme. These impressive differences occurred 13 and 14 years after the initiation of the mass screening programme.

There have been several references recently[3-6] to the fact that no major reduction in mortality from carcinoma of the cervix has been shown to result from a screening programme. But a reduction in mortality caused by the elimination of carcinoma-in-situ from a population would not become evident for approximately 20 years after the introduction of a mass screening programme (allowing 10–15 years for carcinoma-in-situ to progress to invasive carcinoma, and another 10 years or so before this resulted in death). As few screening programmes started much before 1950, these data cannot yet be available. As mentioned in your leading article, figures from Montreal, where screening was started in a small way in 1945, show a considerable increase in five-year survival rates in carcinoma of the cervix, and this is attributed directly to cytology screening.

Though many questions concerning cervical cytology are so far unanswered, or unanswerable, it is to be hoped that efforts to continue the screening of all adult women should not be prejudiced.—I am, etc.,

Coroners' Jurisdiction

SIR,—In his letter (24 June, p. 845) Dr. Ivor M. Jones claims that my letter (3 June, p. 642) was "seriously misleading," and then proceeds to give an account of the facts which is a masterly example of *suppressio veri*. I maintain that "Deaths in the Community" was produced in 1963 by the Forensic Subcommittee, before the Brodrick Committee was set up in 1964. It was received by the Central Consultants and Specialists Committee, but not accepted. It may also be true that the General Medical Services Committee also never considered it in detail.

The answers to the questionary sent to the Association by the Brodrick Committee were given by the Forensic Subcommittee without consultation with the C.C. and S. Committee and also, I believe, with the G.M.S. Committee. Neither these answers nor the evidence to be given to the Brodrick Committee were ever published and were not known to the large majority of consultants and general practitioners.

The Forensic Subcommittee consists of three pathologists, three police surgeons, three general practitioners, and the Secretary of the Coroners Association, but no representative of consultants in general medicine, surgery, obstetrics, or hospital administration.

It was only a few days before oral evidence was to be given to the Brodrick Committee that Dr. Ivor Jones was pressed to accept a representative of the C.C. and S. Committee, and then agreed only "on the understanding that it would not be possible to depart from the general tenor of the evidence which had already been submitted to the Brodrick Committee."

The C.C. and S. Committee took note of this situation and sent my memorandum to the Brodrick Committee.

The Forensic Subcommittee, by virtue of its composition and the autocratic way in which it acted, lays itself open to a charge of special pleading. The members of the Association should have been given the opportunity of deciding whether they would continue to support the present systems of coroners' jurisdiction or would prefer a system similar to the procurator fiscal in Scotland.—I am, etc.,

London W.1. H. A. KIDD.

Aversion Therapy of Homosexuals

SIR,—Dr. M. J. MacCulloch and Dr. M. P. Feldman (3 June, p. 594) state: "The rate of improvement achieved by experienced psychotherapists in comparable series of homosexual patients has in no instance exceeded 27% (Bieber *et al.*, 1962). In our opinion the approximately 60% rate of improvement achieved in our series is mainly due to the use of an aversion therapy technique. . . ."

The 27% statistic refers to the 29 cases in our series of 106 psychoanalytically treated male homosexuals who became exclusively heterosexual. A valid comparison may be made between the group that shifted to exclusive heterosexuality—and only these cases—and the 13 recovered cases (30%) in the authors' series. In our study an additional 16 cases (15%) became actively heterosexual though not exclusively so, bringing the total rate of improvement as judged by sexual status to 42%. In the authors' series seven cases were heterosexual though not exclusively so, bringing their total rate of improvement to 46%, a statistic similar to our own findings. However, the other five cases they list as improved sexually would not be so considered by our criteria. "Two were mixing socially with females and were beginning to approach active heterosexual practice. . . . Three out of the five were improved in the homosexual area and were using strong heterosexual fantasy." The large majority of male homosexuals in the United States, and all the patients in our study, mix socially with females. This does not indicate an ability to have a sexual or romantic relationship with a woman. Nor are heterosexual fantasies, wishes, or beginning approaches to women considered by us to be reliable indicators that a shift in actual sexual behaviour will occur.

The statistics available to MacCulloch and Feldman as reported in our volume,[1] represented the sexual status of 106 patients as of June 1960. In February 1965 I conducted a follow-up study reported at the annual meeting of the American Psychiatric Association on 6 May 1965. Data on the sexual status of 79 of the original 106 cases were obtained. At the outset of treatment 68% had been exclusively homosexual, 28% were bisexual, and 4% were inactive sexually. In February 1965 39% were exclusively homosexual, 21% were bisexual, 34% were exclusively heterosexual, and 6% were inactive. Of the 29 patients who had become exclusively heterosexual as of June 1960 information on 15 was obtained. Of these men 12 had remained exclusively heterosexual for a minimum of five years, while the other three had experienced occasional homosexual episodes during periods of stress, but were married and predominantly heterosexual. There were seven additional patients reported as exclusively heterosexual in 1965 who had not yet become so in June 1960.

The authors state that 30 of their 43 cases had no abnormal psychogenic development. This evaluation is not in accord with our data, where in each of the 106 cases gross psychogenic development and a psychopathological current adaptation were easily discernible. Further, I have personally interviewed at least 200 male homosexuals since the research study and in all instances there were notable disturbances in development as well as in the current life situation. The paucity of data on abnormal aspects of development may reflect the same sort of psychiatric naiveté that, regrettably, is also shown by the authors' use of a simplistic personality typology which includes categories such as "self insecure," "weak willed," "attention seeking."

In developing a relatively new treatment technique the authors would do well to report results factually and in greater detail. Many questions remain unanswered—a primary one being, how many of the 24 cases who had been practising homosexuals for ten years or longer were among the 13 cases who became exclusively heterosexual? We shall await the results of a longer follow-up period with interest before drawing any conclusions about the long-term effectiveness of aversion therapy for long-term homosexuals.—I am, etc.,

Self-expulsion of a Nasal Polypus

SIR,—A man of 70 presented me with a small container, explaining that he had expelled the contents from his nose that morning. It had been accompanied with a mild cough and only very slight epistaxis. On opening the container I found the mass to be a fairly typical nasal polypus, pearly greyish pink in colour and the size of a brazil nut. It had a jelly-like consistency, with one thin lateral blood vessel. It was not freely supplied with blood vessels as is common with polypi and there was no evidence of the existence of a pedicle. I did not find much muco-pus, and examination of the nasal fossae revealed clean mucous membrane and a free airway.

This in my experience is the first occasion of the self-expulsion of a nasal polypus (or it might be the less common papilloma ?). Incredibly, he had no previous symptoms of any nasal obstruction. My patient had unknowingly at the time saved himself from the nuisance of having to undergo a polypectomy.

I write about this case to inquire whether this in fact is indeed a much more common occurrence than has hitherto been realized, and I would be happy to be enlightened by readers who have had similar cases.—I am, etc.,

Woodford Wells,
Essex. BENJAMIN GREEN

Muscle Stiffness and Vitamin C

SIR,—Dr. I. H. Syed's regimen for the prevention and treatment of muscle stiffness following unaccustomed exercise (30 July 1966, p. 304) has also been assessed in a small double-blind trial, which, like that of Drs. J. L. Corbett and A. Barr, reported in your columns recently (8 July, p. 113), has demonstrated no effect.

Seventy-eight young students at a Scottish police college were subjected to a vigorous 50-minute bout of physical exercises under the supervision of an instructor, whose experience was that such a stint invariably produced severe stiffness and discomfort in a majority of his victims the following day. It was decided, therefore, to make the trial period short and compare the effect of ascorbic acid and lactose only on the condition of the subjects the morning following the exercise and later on in the day.

Tablets containing 100 mg. sodium ascorbate or lactose (flavoured with small amounts of bicarbonate to render them indistinguishable from the ascorbate on chewing) were randomly allocated with instructions to take 5 tablets one hour before the exercise and 4 tablets immediately after. Subjects were only required to fill in a simple questionary. The following morning each recorded the degree of muscle stiffness, if any. Those who had recorded stiffness or discomfort took a further 800 mg. of vitamin C over a period of six hours, recording whether the stiffness subsequently wore off or not.

Analysis of results showed that 40 subjects (35 male and 5 female) had ascorbate and 38 (35 male and 3 female) had lactose. Average age of the two groups was 22.8 and 23.7 years. Although the *degree* of muscle stiffness had been recorded, this purely subjective classification was in fact ignored in the final analysis, as it was felt to be unreliable. No significant differences were demonstrated between the two groups in respect of either "morning after" discomfort or the subsequent six-hour trend.

The trial was carried out with the most helpful co-operation of Col. R. C. Robertson-MacLeod, Commandant of the Police College, and the on-the-spot practical assistance of Sgt. Duff, to whom, together with the students who willingly volunteered, I am most grateful.—I am, etc.,

N. T. POLLITT.

Vitamins Ltd.,
London W.6

SIR,—We were interested to read the comments (8 July, p. 113) by Drs. J. L. Corbett and A. Barr, as we too have recently completed a small trial to assess the value of ascorbic acid in relieving the muscular pain of unaccustomed physical exercise. The trial was designed so that one of us (P. T. L.) received an oral dose of either ascorbic acid (1 g.) or placebo. These were randomly distributed and given immediately before severe exercise. The following day the subject was asked to state whether he thought he had taken the placebo or vitamin, on the basis of the effectiveness in prevention of muscle stiffness. The test was performed 12 times at weekly intervals. Nine out of the 12 doses were correctly assessed, but the ratio of 9 correct to 3 incorrect is not statistically significant.

Thus our findings are in line with those of Drs. Corbett and Barr, indicating the ineffectiveness of large doses of ascorbic acid in preventing muscle pain after exercise.—We are, etc.,

Difficult Knee-jerks

SIR,—It is occasionally difficult to elicit a knee-jerk that is not absent. The following tip has been found useful.

The patient sits on the couch with his legs dangling but not touching the floor. Place a hand under the big toe (preferably unshod) and ask him to press it firmly on to your resisting hand; now tap the ligamentum patellae.—I am, etc.,

C. B. FRANKLIN.

Newcastle,
Staffordshire.

The Wheel Turns

SIR,—It would seem that the application of cold water is hailed as the most modern first-aid treatment for burns. Past treatments have led us through the days of vinegar, rum, olive oil, tea infusions, carron oil, tannic acid, and many more up-to-date medicaments till, at last, we have found cold water. But could it be that there are some Rip van Winkles among us who have regained consciousness at last and are talking?

The following quotation from a textbook on surgery may be of interest.[1] It is taken from Chapter V, page 441, entitled "Of Burns." The heading reads: "Sect. II. Of the treatment of burns by the application of cold.

"The means recommended by Sir James Earle consist in the speedy application of cold water, or water cooled by ice, which is to be renewed as often as it becomes warm. The cuticle of the burnt or scalded part is not to be removed; all stimulant and oily applications are to be avoided. By this means, he says, the cure will be accomplished without leaving scars or lameness of the part."

Sir James goes on to point to the advantages of this form of treatment which followed in cases under his care.—I am, etc.,

C. W. A. EMERY.

St. Annes-on-Sea,
Lancashire.

Gluten-free Diets

SIR,—I was very interested to read the letter from Dr. R. F. Fletcher and Miss Cathryn E. A. Hood (13 May, p. 445). The National Pharmaceutical Union has in voluntary membership approximately 11,500 (over 96% of the total) of "private" retail pharmacies in the United Kingdom, and recent experience in our information department, which supplies information on a very wide range of subjects to N.P.U. members, has shown that there is an increased demand for information about gluten-free flour and products. That such information is being sought is a clear sign that N.P.U. members are taking particular interest in patients who need gluten-free flour and biscuits. I was therefore concerned to see that these two groups of products were mentioned in the letter as being available from branches of a large multiple pharmacy. This gives the impression that the products are not available from "private" pharmacies, and this certainly is not the case in our experience.—I am, etc.,

J. WRIGHT,
Secretary.

The N.P.U. Group,
London N.14.

Carcinogenicity of Tobacco and Tobacco Smoke

SIR,—Numerous laboratories have shown that tobacco smoke condensates and extracts of tobacco are carcinogenic when applied to the skin of mice and rabbits; they induce papillomas and carcinomas. These findings have been regarded as another piece of evidence in the case against cigarette-smoking. It has been argued that any agent that can produce cancer in an animal can do so in man. Epidemiological experience on a global scale in the only test animal of any real consequence—namely, man himself—does not, however, support this. Is it not surprising, and indeed significant, that among the millions of tobacco-stained fingers that have been continually contaminated with tobacco smoke condensates and tars in heavy cigarette smokers (20 cigarettes and more per day for 20 years or more) that not a single instance of "cigarette-smoker's finger" (papilloma or carcinoma) has ever been seen or reported? As not all heavy cigarette smokers develop lung cancer, does not this argue for some other essential factor, besides cigarette smoke, for the evolution of malignant disease in any particular heavy cigarette smoker?—I am, etc.,

Cape Town,
Republic of South Africa.

Unexpected Foreign Bodies

SIR,—I have great sympathy with Dr. G. B. Stein (1 July, p. 51), his patient, and the hospital staff concerned. Mr. Derek Stafford and I are just completing a survey of cases where foreign bodies have been swallowed or inhaled in Scotland, Wales, Ulster, Eire, and England in 1964. In 1936 Chevalier Jackson reviewed the 3,612 cases he had treated during the preceding 20 years.[1] In our small series the objects are just as bizarre, but the cases involving dentures are more complicated, since the object cannot usually be seen on *x*-rays. Dr. Stein's castigation of dangerous dentures is quite justified and all the more remarkable since so little attention has been paid to the very many articles, reports, and letters on this subject. Certainly the practitioners and dental laboratory technicians can be blamed for not using a readily available radio-opaque dental plastic; but the blame rests also with teachers of prosthetics in dental schools and the advisers to the British Standards Institute and the Minister of Health. Perhaps the importers and manufacturers of toys will give a lead by insisting on using radio-opaque materials.—I am, etc.,

WARREN HARVEY.

Glasgow Dental Hospital
and School,
University of Glasgow.

Policlinic: Medical Teaching at the Bedside

SIR,—I enjoyed the middle article, "A Look at Swedish Medicine and Neurology," by Dr. Bryan Ashworth (6 May, p. 367). But, though he is writing about Sweden, his use of the word "polyclinic" raises a question of nomenclature with which we in English-speaking countries may have to concern ourselves. The related word "policlinic" is beginning to be heard in this country, and "polyclinic" is sometimes written when "policlinic" is meant; both are entertainingly discussed s.vv. in the *Oxford English Dictionary,* 1909, volume VII.[1]

It is evident that Dr. Ashworth is referring to a city (πόλις) or outpatients' clinic that is headed by consultants, a "policlinic" (in Swedish, as in German, "poliklinik"), and not to a clinic for the diagnosis and treatment of diseases of many (or all) kinds (πολύς, κλίνη). Nowadays, if not quite in Jonathan Hutchinson's time (vide the dictionary, which quotes his definition), the name "polyclinic" would suggest a general practitioner's surgery or dispensary; and, since no practitioner or group of practitioners is likely to have any use for it, should we not ban it? And should we not resist any move to call an outpatients' department a "policlinic"? If we wished to confound patients and staff alike and upset *The Times*, as Jonathan Hutchinson did (vide the dictionary's quotation from the issue of 16 December, 1898), we could of course call that part of it staffed by resident or junior doctors whose duty it is to send patients to the appropriate part of the "policlinic" a "polyclinic." It might then seem odd to *The Times* that titles, whatever they have "come to denote," should be chosen which suggest that the sick rise from their various beds in order to occupy a communal one provided by the city.—I am, etc.,

Peppermint Grove, Western Australia. GERALD C. MOSS

Local Government Reform and the Health Services

SIR,—Since Miss Elizabeth Burney's article (1 July, p. 41) I have been scanning the columns of your journal in order to see if any of my colleagues in the public health service, whom I felt sure would be able to draft a far better letter than I could do myself, had seen fit to reply. After an interval of three weeks a letter has at last appeared, from the pen of Dr. P. O. Nicholas, of Bolton (22 July, p. 239), and I can only endorse the general tenor of his remarks.

When one has spent a not inconsiderable proportion of one's own, albeit relatively short, medical lifetime in acquiring experience and knowledge in order to be the better able to administer the community health services, one does indeed wonder who are these "others" who are going to guide these selfsame services.

I would venture to say that many of my colleagues, who have been similarly engaged in the same pursuits as myself, would seriously question the soundness of further fragmenting these services and the suitability of anyone else to run them in a sufficiently realistic and understanding manner.—I am, etc.,

Shire Hall, Cambridge. PETER SYLVESTER.

Annual Representative Meeting

SIR,—May I endorse Dr. J. D. Shapland's letter concerning the Annual Representative Meeting? It is deplorable that a limited number of "microphone hogs" were allowed to take up the time of the A.R.M. over details which should have been thrashed out elsewhere. This sort of thing has been progressively more noticeable over a number of years, and I am disgusted at the way hospital matters are rushed through in the last hours of the meeting. What hope is there of getting a better deal for hospital doctors? As far as I am concerned the A.R.M. has fallen into disrepute and only drastic reforms will restore its reputation.—I am, etc.,

Epsom District Hospital, Epsom, Surrey. E. N. CALLUM.

*** The Secretary of the B.M.A. states: The Chairman of the Central Committee for Hospital Medical Services has decided to call a special meeting of his Committee in order to debate the motions under "Hospital and Consultant Services" which were not debated at the A.R.M. at Bristol. The Divisions that proposed the motions will be invited to send representatives to the meeting.—ED., *B.M.J.*

Degrees of Seniority

SIR,—Senior hospital medical officers will welcome the news that the Central Consultants and Specialists Committee has agreed to support the resolution from the S.H.M.O. Group Executive Committee that in the event of any future pay award to medical assistants the existing differential between the salary scales of the S.H.M.O. grade and the medical assistant grade should be maintained (*Supplement*, 15 July, p. 67).

The reason for this resolution should be made clear—namely, that senior hospital medical officers are recognized as of senior status with duties and responsibilities above those of medical assistants, the latter being responsible to named consultants and of intermediate grade (H.M. (67) 26).—I am, etc.,

NORMAN V. WILLIAMS.

Cefn Mably Hospital, St. Mellons, Nr. Cardiff.

B.M.A. as a Negotiating Body

SIR,—The Representative Body at Bristol debated for two hours on Saturday morning, 8 July, a dispute with the Junior Hospital Doctors Association (22 July, *Supplement*, p. 69). It was revealed in the debate that the J.H.D.A. had previously published actionable matter about B.M.A. negotiations, but neither had action been taken against the J.H.D.A., nor, apparently, had the J.H.D.A. been warned about the effect repetition would have on future negotiations.

Now, if the B.M.A. is going to speak to outside bodies, and subsequently negotiate on their behalf, then surely it must establish a code of conduct as a prologue to any such negotiations. If outside bodies are going to use B.M.A. personnel and their resources to help achieve a common objective then the B.M.A. is entitled to, and indeed must, place some restriction on published criticism for the duration of the negotiations.

It was ironical that on Monday, 10 July, the Representative Body should have voted heavily against having non-B.M.A. members on regional councils. The R.B. thus refused to give these non-members the advantages of the resources of the B.M.A. Yet it would appear that what they had refused to do at regional level was already being done with the J.H.D.A. centrally, at the highest level, even to the extent of negotiating on their behalf with the Minister. The status of these negotiations with the J.H.D.A. needs defining.

I do not advocate that the B.M.A. should refuse to negotiate with and on behalf of outside bodies, but I do believe that outside bodies must first recognize their responsibilities towards the B.M.A. in terms of their own behaviour and publications.—I am, etc.,

Leeds. JOHN D. SINSON.

Radio Communication and the G.P.

SIR,—I was surprised that in the interesting article "Radio Communication and the Emergency Department" (15 July, p. 170) by Dr. M. H. Hall and Mr. R. S. Garden there was no mention of a link with the general-practitioner service. More and more family doctors like myself are availing themselves of the great help of a radio transceiver in their cars. This is particularly true in areas where the Emergency Treatment Service is active.

It would be of benefit to general practitioner and hospital alike if there was a means of communicating with the hospital directly from the general practitioner's car. In many hospitals there is a relay unit for direct communication with the ambulance service. It would be easy to adapt this system to communicate with the family doctor, except for the fact that the frequencies used are usually too dissimilar.

It is hoped that the committee considering the equipment of the ambulance service, and bodies controlling other medical radio links, will bear in mind the general practitioner and his needs in this connexion.—I am, etc.,

Glasgow. KENNETH HARDEN.

Points from Letters

Opportunities in British Medicine

Dr D. C. G. BETT (Farnborough Hospital, Kent) writes: I see in your issue of 15 July (p. 128) that the Ministry of Health intends to send a team to North America to try to persuade British doctors there to return home.

I think many of us still in Britain would be interested to know what this team is going to say to these expatriates. We have listened to many fine words from the Ministry, but when these have been translated into actual practice the result is usually very far short of the original promise. If Dr. R. H. Barrett and his colleagues have anything real, which is likely to attract doctors back to Britain, I feel that the good news might be made public now.

Casualty Department—or G.P. Service?

Mr E. P. ABSON (Ryde, Isle of Wight) writes: It is circumstances and not the diagnosis which determines attendance, and the casualty department must be capable of dealing with the immediate needs in many different specialties (1 July, p. 46). Well over 50% of the work and the main responsibility are in making the diagnosis, and, more difficult and important, eliminating more serious diagnoses over a wider spectrum. A man who has fallen 50 ft. (15 m.), and (if the "missed injury" is not to be missed) any case of general trauma, requires full examination and perhaps observation, even though the final conclusion may be "bruise—no treatment."

Obituary Notices

H. STOKES, O.B.E., M.D., F.R.C.S.I.

Mr. H. Stokes, a past-president of the Royal College of Surgeons in Ireland, and the last of his line to be associated with the Meath Hospital, Dublin, died there on 3 July at the age of 88.

Henry Stokes was born in India on 11 January 1879, his father being in the Indian Civil Service. He was brought up and educated in Dublin. He had five sisters and two brothers: of the latter, Brigadier "Bill" Stokes is still alive, and Adrian, the youngest, having won distinction for his bacteriological and pathological work in the first world war, died in West Africa of the yellow fever which he was investigating. Henry was educated at Trinity College, Dublin, where he graduated M.B., B.Ch. in 1903, proceeded M.D. in 1905, and obtained the Fellowship of the R.C.S.I. in 1907. He studied in Berne, Leysin, and Basle on a surgical travelling prize, and later in the Mayo Clinic, U.S.A. He was elected surgeon to the Meath Hospital in 1912, and was later consultant surgeon to the National Children's Hospital, St. Ultan's Infant Hospital, and Cork Street Fever Hospital, Dublin. He eventually resigned his appointments in 1956. During the first world war he served in the R.A.M.C. as lieutenant-colonel, and was appointed O.B.E. in recognition of his services. He was president of the Royal College of Surgeons in Ireland from 1940 to 1942.

He was very appropriately M.D., and his approach to his patients was that of the medical adviser who was ready and able to operate if necessary. He was a sound and versatile surgeon who loved to improvise instruments to meet special cases, such as using the rib of an umbrella to follow the track of a bullet through the abdomen before opening it. As a teacher he kept his students well aware of the history of medicine and the Meath Hospital.

Henry had many interests. He was a keen shot, and was a good and keen fisherman; he was an antiquarian, and a collector of many things from old books to the skeletons of the extinct giant Irish elk, of which he discovered quite a large number; he amassed friends, and had very many in and out of the medical profession. He was the least commercial of surgeons, devoting his best attention to the poor in Dublin, and is remembered with affection by his patients, colleagues, and all who knew him.

He married in 1911 Kitty Franks, and had a son, a daughter who is a doctor, and another daughter who is an excellent artist.
—B. O'B.

S. W. MASLEN-JONES, M.S., F.R.C.S., F.R.C.O.G.

Mr. S. W. Maslen-Jones, adviser to overseas candidates for the Royal College of Obstetricians and Gynaecologists and a former vice-president of the College, died at his home in Tettenhall on 17 July. He was 75.

Samuel Walter Maslen-Jones, the son of a Baptist missionary, was born in Simla on 6 September 1891, and was educated at Eltham College, and at the Middlesex Hospital, London, where he qualified with the Conjoint diploma in 1914. During the first world war he joined the R.A.M.C., and saw four years service in Egypt, where he was mentioned in dispatches, and where—in Cairo—he met and married Sister Kate Wilde, Q. A. I. M. N. S. After demobilization he graduated M.B., B.S. in 1919, and took the M.S. and the F.R.C.S. in 1920. He went to Wolverhampton to work with Frederick Edge, and in 1921 was appointed to the staff of the Women's Hospital there. During the years of his work in the West Midlands he gained an outstanding reputation, founded not only on his ability and skill as a diagnostician and operator but on the sympathetic understanding and kindliness of approach to all with whom he came into contact. He was a past-president and honorary Fellow of the Birmingham and Midland Obstetric and Gynaecological Society, a one time chairman of the South Staffordshire Division of the British Medical Association, and president of the Staffordshire Branch from 1937 to 1940. In his own specialty he was a foundation member of the British College of Obstetricians and Gynaecologists—as it was then called—and in 1931 was elected to the Fellowship. He was chairman of the building committee responsible for the construction of the new college house in Regent's Park, and was a vice-president of the College from 1958 to 1961. Among his many interests outside medicine, he was on the governing council of the Royal Masonic Boys' School, and for the year 1966–7 was president of the Old Boys' Association of Eltham College.

Maslen's interests and hobbies were innumerable, as were his friends. He had a great capacity for making and retaining friends, and his popularity was immense. He was also considered one of the best after-dinner speakers in his part of the country. In his student days he played rugby for the Middlesex Hospital, he was a good tennis player, and for years played off a handicap of 12 at golf. His annual ski-ing holiday was a great joy to him, his support of the "Wolves" keen and regular, and for the last 25 years he had become an ardent trout and salmon fisherman. Even in the gardening with which he had interested himself since retirement, he was, as ever, a perfectionist.

There are many who mourn Maslen. To his widow and three sons and their families a very real sympathy is extended.—H. J. M.

Dr. VICTOR RUSSELL writes: Maslen, as he was affectionately known to us all, was not only a great man, a prominent Freemason, and a fine surgeon but also a warm and friendly person, and a true friend. His kindness and helpfulness will be long remembered, and I think his general-practitioner colleagues in Wolverhampton will never forget the strong support than he, together with two or three others, afforded them in the struggle before 1948; and this at a time when most consultants, well satisfied with the terms of service they had been able to negotiate, had little time or sympathy to spare for their general-practitioner brethren. Those of us who knew him well feel that we are the better for having known him, and that the world is diminished by his passing.

W. DUNLOP, O.B.E., M.B., CH.B. D.T.M.&H.

Dr. W. Dunlop, a former professor of clinical therapy and lecturer in diseases of children at the Royal College of Medicine, Bagdad, died at his home at Tillingham, on 30 June. He was 80.

William Dunlop was born on 14 September 1886, and received his medical education at the Universities of Dublin and Edinburgh, graduating M.B., Ch.B. in 1909. He had a varied career, much of it being abroad. On the outbreak of the first world war he joined the R.A.M.C., and most of his service was in Mesopotamia, where he commanded various hospitals and took part in the advance on Bagdad, and was promoted major. He was three times mentioned in dispatches, and was appointed O.B.E.(Mil.) in November 1918. He transferred to the Civil Administration, and was appointed chief medical officer, civil hospitals, in March 1919, and in April of that year was appointed director of the Bagdad General Hospital, a post which later included being professor of clinical therapy and lecturer in diseases of children at the Royal College of Medicine. In 1924 he took the D.T.M.&H. He remained in Iraq until 1935 and for his distinguished services there he was given the Order of the Nahdhah by the Iraq Government. On his retirement he was presented with the Order of the Rafidain by the King of Iraq.

On the outbreak of the second world war he again returned to the R.A.M.C., and remained in it until July 1945, after which he was appointed a member of the Pensions Appeal Committee, and in 1947 chairman. He retired in 1956.

Willie, as he was known to all his friends, had many interests apart from his profession, which always came first. He was widely read, and probably his main hobbies were bird-watching and shooting. He was an outstanding authority on the birds of Iraq, and we were always amused at his little " pocket duck book," which he carried to identify the remarkable number of migrant ducks which visited the country. There was rarely a shooting day (once a week) when the guns were not asked back to his house, and entertained by his wife to a sumptuous tea.

I cannot imagine him being ruffled by anything, and impatience, anger, or neglect were not in his character. Above all, he had a great sense of humour, probably due to his Irish blood. He was a great man, beloved by British and Arabs alike.—T. H. McL.

H. J. GIBSON, M.D., D.P.H.

Dr. H. J. Gibson, consulting pathologist and director of the Bath clinical area central laboratory, died on 6 June. He was 62.

Hubert John Gibson was born in King's Lynn, Norfolk, on 22 October 1904, but his family moved to Isley, Argyllshire, where the firm foundation of a Scottish education was laid in the village school. In 1914 the family moved again, this time to Edinburgh. There he continued his education, first at George Watson's College and later at Edinburgh University, where he graduated M.B., Ch.B. in 1926. In the postwar era the large backlog of able medical graduates gave rise to delays in obtaining house appointments at the Royal Infirmary. Gibson decided, therefore, to fill in the waiting time in general practice. This took him to the West Riding coalfield of Yorkshire, where he experienced the difficulties of the general practitioner working divorced from the help of ancillary medical services. He was also moved by the plight of those with advanced rheumatoid and allied diseases, which he now met for the first time. Undoubtedly these experiences influenced his future career, both as regards his continuing interest in the clinical side of pathology, which in turn enabled him to help his colleagues at the bedside, as well as his special interest in the pathology of rheumatic conditions.

In 1927 he returned to Edinburgh, took the D.P.H. in 1929, and was invited to join the university staff in the department of bacteriology under the late Professor T. J. Mackie, where he soon made his mark, becoming lecturer in the department. During this period he published work on the natural antibodies of man and animals, on the isolation of enteric organisms from sewage, and on the transmission of louping-ill virus. He proceeded M.D. with high commendation in 1935. In the 1930s his work with streptococci directed his interests to the rheumatic diseases. Although by this time he had every prospect and promise of going further in academic bacteriology, he accepted an invitation to establish a department of pathology at the Royal National Hospital for Rheumatic Diseases at Bath, and in 1935 crossed the border. From this time onwards he made numerous regular contributions to the literature of the pathology on rheumatic disorders and established a world-wide reputation. He was an excellent administrator, and after the second world war was appointed area pathologist. In this capacity he was responsible for planning an area central laboratory capable of providing laboratory services for the Bath clinical area. The laboratory was built in 1952.

Among the many offices he held were Chairman of the Bath Division of the British Medical Association in 1948–9, president of the Clinical Society of Bath, and chairman of his hospital's medical staff committee. He was a founder member of the Bristol Bone Tumour Registry, a founder Fellow of the College of Pathologists, and a member of the Heberden Society.

Hubert Gibson happily combined his first-class brain with a pleasing personality and an outsize sense of humour. He had a most infectious laugh. If at times inclined to be quick-tempered, and unwilling to bear fools lightly, his innate kindliness would quickly reassert itself, and it is true to say that he had many friends and no enemies. By any standards a first-class general pathologist, he will be remembered widely as one of the last of the true clinical pathologists, always interested in the patient, and always preferring to work at the bedside. The logical marshalling of the evidence presented in his detailed reports, invaluable to the harassed clinician, was a further illustration of his clarity of mind. He was always up to date as the result of prodigious reading, extensive travelling to other centres, and a generally inquiring mind. He had the quality, unfortunately rare nowadays, of enthusiastically embracing new ideas and the new scientific approach to medical problems, without relinquishing his attachment to bedside medicine. He loved travelling, and was as interested in the contemporary scene as he was in the relics of bygone civilizations. He had an abiding interest in music, and was a loyal Churchman.

In 1934 he married Enid Spurrier, a talented musician, who survives him with their three children. His only son, Derek, is a member of the medical profession.—D. W. P. and L. C. H.

I. N. S. writes: Having known Hubert Gibson since we were at school together in the early 1920s, I know what a fine man we have lost. He was then that rare bird a boy of English parentage at a Scottish school, and it was interesting to see how keen, for instance, he was on cricket, which is not so popular in Scotland. He himself was no mean cricketer. Another abiding interest which he shared with his wife was music; and they had marvellous summer holidays in far away and unusual places. Many will miss him.

M. C. MACQUEEN, M.B., CH.B. F.F.A. R.C.S.

Dr. M. C. Macqueen, a consultant anaesthetist at the Royal Infirmary, Edinburgh, died on 27 June at the age of 59.

Malcolm Campbell (Callum) Macqueen, a son of the manse, was born on 4 October 1907, and was educated at the Royal Academy, Inverness, and at Edinburgh University, graduating M.B., Ch.B. in 1935. For some years he practised in Elgin and Inverness, until the second world war, when he joined the R.A.M.C. and served in the Middle East and in Italy. On demobilization he pursued his special interest in anaesthetics, took the D.A. in 1947, and the F.F.A. R.C.S. in 1955, and thereafter devoted his whole professional life to his chosen specialty. His services were greatly in demand by his colleagues in Edinburgh, where it was quickly recognized that his technical skill was matched by his sympathetic interest in the human problems of his patients.

Outside his profession he had many interests, and throughout his life maintained a tremendous enthusiasm and zest for living; in spite of failing health he remained a keen supporter and office bearer of the Scottish Gun Club, and was for many years president of the Edinburgh University Shinty Club and the University Hockey Club. Callum Macqueen was an outstanding individualist who will be remembered by his associates for his fearless and outspoken debunking of the bogus and insincere. His many friends will cherish the memory of his constant thoughtfulness and simple acts of kindness, his stout opposition to injustice, his hospitality, his courage, and his integrity.

We offer our sincerest sympathy to his devoted wife and two sons.—G. K. M.

J. H. MELLOTTE, M.B., B.CH., B.A.O.

Dr. J. H. Mellotte, a well-known London ophthalmologist, died in his sleep on 8 July at his home at Walton-on-Thames, where he had practised ophthalmology since 1940. He was 74.

James Henry Mellotte was born in Co. Mayo on 3 October 1892, and after leaving school at Rochestown, Co. Cork, went on to the National University in Dublin to read law. He switched from law to medicine, and graduated M.B., B.Ch., B.A.O. in 1920. Soon after graduating he came to live in England, but after general practice in London until 1936 decided to specialize in ophthalmology, and was subsequently for many years chief clinical assistant at the Royal Eye Hospital, and in the ophthalmic department of the Royal Waterloo Hospital, in London.

Within his chosen specialty Mellotte concentrated his considerable abilities in the art of refraction, and it is not too much to say that he was at one time rightly regarded as a master in this field. He also made a special study of migraine at a time when there was little interest in the subject. His contributions to the medical press were of value in both diagnosis and treatment of this devastating and common complaint.

Throughout his professional life Mellotte was deeply concerned with medical politics, and was for years a much valued B.M.A. representative and committee-man. He served not only on the Ophthalmic Group Committee but also on the Public Medical Services Subcommittee and the Standing Subcommittee on Ophthalmology. He was chairman of the Lambeth and Southwark Division of the B.M.A. from 1931 to 1934. As one of the very early members of the old National Ophthalmic Treatment Board (which through the B.M.A. formed and administered the National Eye Service until the advent of the N.H.S.), he became in turn one of the first ophthalmic medical practitioners to form, with the dispensing opticians, the N.O.T.B. Association. This association he served as a council member until his death. It was inevitable that in these spheres his strong controversial views and outspokenness should bring him into open conflict with a number of his colleagues, with whom he was ever ready to enter the fray, but always with wit and obvious enjoyment.

A man who had an undeniable fondness for the good things of life, and one in whom it was always possible to discern the Dublin medico of the St. John Gogarty tradition—he wrote for the *B.M.J.* a memorable obituary notice of Gogarty in 1957—Mellotte was none the less a lifelong and devout churchman, and was well known in the Catholic community in England. He served also in the Territorial Army as a captain in the R.A.M.C.

There is no doubt about Mellotte's considerable professional and intellectual attainments, and these should perhaps be seen and remembered in the light of what he himself wrote of his old friend, St. John Gogarty—namely, that he was "very Irish in temperament and character"—words which certainly applied to James Mellotte himself, and which he would no doubt be happy to have for his own epitaph. In spite of the burden of increasing years and failing health he worked tenaciously and bravely to the end, and in fact saw his last patients on the very morning of his death. We shall always remember him.

Mellotte married Hélène, daughter of Sir Robert Wallace Best, K.C.M.G., of Melbourne, and is survived by her, and by their two sons and two daughters. Our sympathy to them, and to the grandchildren, in their bereavement is very sincerely offered.—V.P.

C. DE W. KITCAT, M.R.C.S., L.R.C.P.

Dr. C. de W. Kitcat, formerly consultant chest physician in the South and West Somerset clinical area, died in Taunton on 4 July at the age of 67.

Cecil de Winton Kitcat was born on 4 June 1900. His education was interrupted by the first world war, in which he served as a midshipman in the Royal Navy, executive branch. After demobilization he entered St. Bartholomew's Hospital, London, qualifying with the Conjoint diploma in 1923. He subsequently held house appointments at the Connaught Hospital, the West End Hospital for Nervous Diseases, and the Brompton Hospital. An appointment as resident medical officer at the Brompton Hospital followed, and he was able to continue his interest in chest diseases when appointed assistant physician at Fairlight Sanatorium, which he combined with general practice at St. Leonards-on-Sea. He later moved to Highgate, in North London, and at the outbreak of the second world war he rejoined the Royal Navy. He saw active service, and had to swim for his life when H.M.S. *Hecla* was sunk in 1943. Finding another vessel floating near by with the stern blown off, he clambered aboard and was subsequently taken to Gibraltar. Serving under Dr. W. D. W. Brooks at the Royal Naval Hospital, Chatham, he renewed his dealings with chest diseases, and after demobilization took up an appointment as tuberculosis officer with the Somerset County Council. This led to his appointment as consultant chest physician with the South-west Regional Hospital Board, covering Taunton and the south and west of Somerset. He retired in May 1965.

His breezy approach and jaunty manner won him wide acclaim. Many patients, and their family doctors, had occasion to bless his shrewd diagnostic acumen and the effective treatment he meted out. About 18 months before retiring he suffered a myocardial infarction, from which he never fully recovered, and which restricted his activities on retirement.

He leaves a widow, Kitty Meg, to whom our sympathy is extended.—B. J. D. S.

J. T. ANDERSON, M.B., CH.B. D.T.M.&H.

Dr. J. T. Anderson, assistant health adviser, Aden, died suddenly in Aden on 14 May, aged 33.

James Terry Anderson was born on 11 November 1933, and received his early education at Robert Gordon's College, Aberdeen, where he distinguished himself both in the classroom and on the sportsfield. He was also an active member of the Army Cadet Force. In his final year at Gordon's he was appointed school captain, and won the Otaki shield as the best all-round boy. This shield carries with it a trip to New Zealand. He received his medical education at Aberdeen University, graduating M.B., Ch.B. in 1957. While a student he took an active part in the students' representative council, and was a very popular participant in the annual student shows—popular both because of his fine baritone voice and because of his comic ability. As a student he won several awards in the local music festivals, where he sang opera and oratorio with the same competence as he did the Scots songs which he loved. Later in his career he also appeared as a singer on Grampian Television. After graduation he was a resident in the City Hospital and the Royal Infirmary, Aberdeen.

On starting his National Service he volunteered for service with Trucial Oman Scouts, during which time he learned to read and write Arabic. On returning to Britain he entered general practice in Bucksburn, Aberdeenshire. He remained in this post for three years, being very much liked by his patients, for whom he worked very hard. Four years ago he decided to return to Arabia, where he did two terms of duty, first in charge of a hospital in Lodar in Aden, and latterly as health adviser in Mukalla. During the period of leave between his two terms he studied at Liverpool University and took the D.T.M.&H. in 1965. He was to have returned to Liverpool University as an assistant lecturer in tropical medicine but for his untimely death. During his term in Mukalla he was undertaking a massive programme among schoolchildren to eradicate tuberculosis.

To those of us who knew Jimmie at school and at University, the loss is irreplaceable.

In 1958 he married Anne Greenwood, and to her and their two children, Susan and John, we extend our sympathy.—G. E. A.

I. DAVIES, L.R.C.P.&S.ED. L.R.F.P.S.GLASG., D.M.R.E.

Dr. I. Davies, formerly a radiologist at Swansea General Hospital and Eye Infirmary, died at his home in Llandyssul, Cardiganshire, on 29 June after a long illness patiently borne. He was 75.

Iwan Davies was born on 7 November 1891, and received his medical education in Edinburgh, qualifying with the Scottish joint diploma in 1917. After holding a resident appointment at the Aberystwyth General Hospital he proceeded to Liverpool to study radiology, a subject he was to adopt as his specialty. In 1922 he was appointed radiologist to the Swansea General Hospital, where he established the first radiotherapy department in Wales and served on the hospital's house committee for 24 years. He took the D.M.R.E. in 1925. He held the appointment of radiologist to Haverfordwest, Carmarthen, Llanelly, Gorseinon, Morriston, and Neath Hospitals. As radiologist to the pneumoconiosis unit he initiated special studies on anthracosis among south Wales coal miners. He was chairman of the Swansea division of the British Medical Association in 1937–8.

Dr. Davies's calm and genial personality endeared him to his patients, whose natural fears he allayed during his special investigations of their diverse illnesses, and whose weakened hope he sustained and strengthened should they prove in need of prolonged radiotherapy. In his earlier years he was a keen golfer, playing off a handicap of two. He was an ardent fisherman, a devoted gardener, a close student of wild life, and a lover of the countryside and its lore. A deacon of his chapel, he possessed a simple and firm faith. He supported wholeheartedly all good causes and befriended the lowly and the needy. In all his dealings he practised the tenets of a wayside religion. He will be missed by a wide neighbourhood, by his relatives and many friends, and especially by his widow, whose loss is greatest.—W. E.

C. E. HARRISON, M.B., B.S.

Dr. C. E. Harrison, formerly in general practice at North Elmham, Norfolk, died in hospital on 21 May. He was 75.

Cyril Edward Harrison, the son of a metal merchant in Drury Lane, was born in London on 6 November 1891. He received his medical education at the Middlesex Hospital, and after qualifying with the Conjoint diploma in 1915 joined the R.A.M.C. and saw active service at Gallipoli and in Malta, India, China, and at Vladivostok. On demobilization in 1919 he graduated M.B., B.S., and in May of the same year married Miss Muriel Rarkham of Q.A.R.A.N.C. In February 1920 he took over the practice of his father-in-law, Dr. A. Rackham, at North Elmham, where he carried on single-handed an extensive rural practice until 1951, when he was joined by his nephew Dr. Esmond Earle. In 1958 he retired from practice to live in the south of England.

Dr. Harrison was an active member of the British Medical Association, serving as chairman of the East Norfolk Division in 1956–7, and as a member of the local committee of that Division. He kept up to date in medical work by regular attendance at meetings of the local medical society.

To those who knew him well Dr. Harrison was a quiet, unassuming, extremely competent, conscientious family doctor with the formal manner of his days. Meeting him in consultation was always a pleasurable experience, and one was impressed by the trust and confidence so obviously given him by all his patients in every situation of life. His hobbies were music—he was a proficient pianist—and gardening, the latter being shared by his wife, to whom in her loss the sympathy of all his friends and colleagues is extended.—B. B. M.

Z. GREEN, L.R.C.P.&S.I., L.M.

Dr. Z. Green, formerly in general practice at Paddington, London, died while on holiday in Eastbourne on 3 July. He was 75.

Zelick Green was born in Dublin on 1 September 1891, and educated at Wesley College, after which he served an apprenticeship with a firm of chemists, qualifying as a dispensing chemist in 1913. At the outbreak of the first world war he volunteered to go to France as a hospital dispenser with the British Red Cross Society, and was awarded the Mons Star for his services. He returned to Dublin in 1915, and received his medical education at the Royal College of Physicians and Surgeons in Ireland, qualifying in 1920. Shortly afterwards he entered general practice in East London, and became a clinical assistant at the London Jewish Hospital. In 1930 he succeeded Dr. A. J. Cronin to the practice in Paddington where he continued until his retirement in 1960. He was also a clinical assistant at the West London Hospital, a member of the disablement panel, and during the second world war medical officer to the Civil Defence services.

An active member of the British Medical Association, he was a representative at the Annual Meeting in 1955–6, and chairman of the Paddington Division from 1954 to 1962. He was a member for some years of the London Medical Committee. His particular interest was the Paddington Medical Society, which he created and organized for many years. He was also the originator of the Irish Jewish Medical and Dental Society, which was his particular invention, and for several years he was chairman at its happy functions. Much of his spare time was given to the activities of the Jewish Lads' Brigade, of which he was medical officer, and he was always ready to help the youngsters in any way he could.

Dr. Green had a happy retirement, and he kept his interests in his friends and family to the end, and, above all, maintained a most delightful sense of humour and kindliness towards those with whom he came in contact from all walks of life. Although latterly his health was deteriorating, he never lost his great qualities, and the end came in the way he would want it, peacefully and quickly.

He is survived by his widow and two sons, the elder of whom succeeded him in the practice in 1960.—L. M. G.

J. G. writes: Dr. Green, affectionately known as "Jack," was held in the highest esteem by patients and friends alike. Even to this day many of his former patients will remember with gratitude the individual care and attention he bestowed upon them. He took a leading part for many years in bringing about in London a reunion of graduates of Irish medical and allied professions. He was a delightful postprandial raconteur, his speeches being full of Irish wit and jocularity. He was proud of his Irish birth.

Sir EARDLEY HOLLAND, LL.D., M.D. F.R.C.P., F.R.C.S., F.R.C.O.G.

A. W. B. writes: Sir Eardley Holland's achievements (obituary, 29 July, p. 313) during a distinguished career are well known to the profession. Having known him as an intimate friend since the early 1920s, I wish to write about his personal qualities. Eardley had a genius for friendship, which was evident in all the gatherings of his colleagues, owing to his lively interest in their affairs and work and a capacity for real affection for his close friends. He was personally attractive by his distinguished appearance, his welcoming smile, and melodious speaking voice. Wide reading had endowed him with powers of discussion and conversation on almost any subject of intellectual interest. I recall the delight of our monthly dinners, alternately at my flat in Wimpole Street and his club in St. James's. After dinner, if at the club, we would return to the flat and enjoy talk on literature, the arts, history, and the career of men until nearly—or even after—midnight. From his knowledge of literature he developed a style of writing English which was almost pedantic in the careful choice of words, phrasing, and composition; elegant, lucid, and to the point. This became very evident to me during the two years or so when Eardley and I were associated in editing the two volumes of *British Obstetric Practice*, and the companion gynaecological volume. Very carefully did he read the chapters of the contributors, ready, occasionally to their annoyance, to correct slipshod or woolly English.

For me Eardley possessed the charm of manner and companionship which made our meetings so enjoyable, but he was not immune to an irritable impatience with what he considered to be inferior work, the slackness of unfulfilled promises, or what he thought were loose, untidy, or thoughtless opinions. During the home and foreign tours of the Gynaecological Visiting Society Eardley was at his best as a cheerful member, mixing with all of us, and sometimes as the efficient manager of a party of 20 or more which included at least one or two who were not renowned for their idea of punctuality.

Despite his recent incapacity, I feel keenly the loss of his friendship over some forty years or more. My sympathy goes out to his beloved wife, Olivia, and to his three daughters.

Sir ALEXANDER MACGREGOR

K.B.E., LL.D., M.D., F.R.C.P.GLASG., D.P.H.

C. M. S. writes: Sir Alexander Macgregor (obituary, 15 July, p. 181) encouraged, and quietly expected, every member of his staff to take a special interest in one particular branch of preventive medicine, and to undertake research. When a paper was submitted Dr. Macgregor, as we then knew him (or "A. S. M.," as he was affectionately referred to), would ask the aspiring young author to meet him after office hours for a light (very light) evening meal in one of the near-by city tea rooms, and then to return for a couple of hours spent on a detailed reading and suggested improvements of the paper—all this after a punishing day's work as head of a huge department. These evening sessions would be repeated until the paper was, in his view, fit for publication. His approach to all would-be contributors was: "Where are your facts ?" Speculation and surmise were blue-pencilled, only facts and reasonable deductions were passed.

He knew how to divest himself of the day-to-day chores of his office, which were handled by a competent lay secretary. One trait I admired: any general practitioner in the city who was asked to speak to him personally on the telephone was put through at once. He was truly one of the great leaders of the public health service, and it was a cherished privilege to have been trained by him.

Sir CLAUDE FRANKAU, C.B.E. D.S.O., M.B., F.R.C.S.

Sir TREFFRY THOMPSON writes: Others have paid tribute to Claude Frankau's skill as a general surgeon (obituary, 8 July, p. 116), but it is to him as the surgical registrar at St. George's before the first world war that I would like to pay special tribute, a period when I knew him first and best. He was a wonderful teacher to whom nothing was ever too much trouble so long as he could make sure that we understood the reason for a diagnosis or the details of an operative procedure. Not that he endured fools gladly. After some particularly fatuous answer to some question he would slightly cock his head to one side and cast a quizzical look at the idiot, and would then make sure that the idiot got the facts or the details right. Even in those days we all owed him a tremendous debt for his teaching.

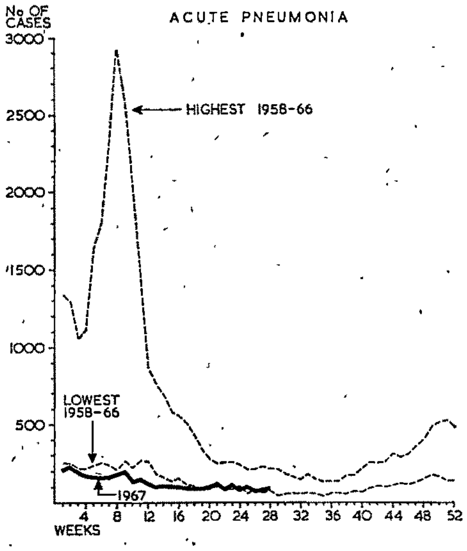
Births and Deaths in the June Quarter

The birth rate in England and Wales during the June quarter was 17.9 per 1,000 population and was 0.1 below the rate for the preceding June quarter. Stillbirths reached the low level of 14.6 per 1,000 total births, being 0.4 below the rate for the second quarter of 1966. The death rate was 10.8 per 1,000 population and was 0.2 below the rate for the preceding second quarter. Infant mortality was 18 per 1,000 live births.

Graphs of Infectious Diseases

The graph below shows the uncorrected number of cases of acute pneumonia in England and Wales. Figures for 1967 are compared with the highest and lowest figures for each week in the previous years shown.



INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending **15 July** (No. 28) and corresponding week 1966.

Figures of *cases* are for the countries shown and for Greater London. Figures of *deaths* and *births* are for the whole of England and Wales (London included), Greater London, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

MEDICO-LEGAL

Complaints by Patients

[From our Legal Correspondent]

A patient whose complaint is accepted by a service committee under the National Health Service (Service Committees and Tribunal) Regulations, 1956, cannot appeal to the Minister on the ground that the penalty imposed was too small.

Dr. Jacob Ellis, of Barnsley Road, Sheffield, was granted[1] an order of prohibition by the Divisional Court of the Queen's Bench Division ordering the Minister of Health not to hear a purported appeal by Mr. Ernest Harrison, of Neepsend, Sheffield. Mr. Harrison had made a complaint to a service committee. The service committee reported to the executive council that it found Dr. Ellis in breach of his terms of service. It was recommended that £5 should be withheld from Dr. Ellis's remuneration. Mr. Harrison felt that £5 was too small a sum and wanted to appeal to the Minister on that account.

Regulation 7 (2) of the 1956 Regulations provides that any dissatisfied party is entitled to appeal to the Minister against the Council's decision. The Divisional Court held that a party who had in effect won on the only issues that concerned him was not a dissatisfied person within the meaning of the regulation and had no right of appeal. Had the complaint been rejected Mr. Harrison would have had a right of appeal. But the complaint had been found proved. The decision of the Council about what action, if any, should be taken upon that finding was not a matter in which the complainant had an interest. A complainant would have an interest in such decision only if he alleged that he had incurred expenses as a result of the breach and sought to recover them under the regulations. In granting the order of prohibition, the Court allowed Dr. Ellis his costs against the Minister.

PARLIAMENT

Abortion Bill: New Conscience Clause and Title

[From our Parliamentary Correspondent]

Two of the House of Lords' amendments to the abortion law reform Bill have put it in jeopardy. The House had the Bill before it on the committee stage on 26 July, and passed an amendment requiring that one of the two doctors giving an opinion on lawful termination should be a Health Service consultant or a doctor approved by the Minister of Health. The other amendment, carried by one vote, was to delete the words "or any existing children of her family" (subsection (1) (a) (i)).

Changes in the Bill—and the second change referred to is vital to its structure as M.P.s passed it—require that it shall go back to the Commons for their agreement. This must now be in the single week at the end of October, when Parliament returns from the summer recess to tidy up the odds and ends of legislation before starting on a new session. The time will be shortened by the fact that the Lords have to push the Bill through its report and third reading. An obdurate opposition could still foil the promoters' hopes of seeing this measure become an Act of Parliament before the current session ends.

These considerations were in the mind of **Lord Silkin**, piloting the Bill, when early in the debate he said, "We must face the fact that time is against us, and if we pass any amendments of which another place [House of Commons] does not approve we shall effectively kill the Bill." He asked the House to accept the Bill as it stood.

Type of Doctor

The first issue discussed was the status of the two doctors on whose opinion, as declared in Clause I (I), a termination should be lawful. The clause requires simply two registered medical practitioners.

Lady Summerskill proposed that one of them should be named on a list approved by the Minister of Health. **Viscount Dilhorne** and others wanted one of them to be "employed under the National Health Service as a consultant or approved by the Minister of Health or the Secretary of State for the purpose." **Lady Wootton of Abingdon** thought one of them should be specially qualified in psychological medicine.

For the Government **Lord Beswick** enumerated a number of defects which the Ministry of Health saw in all these proposals, and reminded the House that the Minister had refused to accept the responsibility of making invidious distinctions between doctors. **Lord Silkin** said the Bill as it stood was right, pointing out that the operation must be carried out in a Health Service hospital or an institution approved by the Minister, and approval must include suitable staff.

Lady Summerskill withdrew her amendment; Lady Wootton did not move hers; and Viscount Dilhorne's was carried by 116 votes to 67.

"Serious" Risk

Lord Segal tried to amend paragraph (a) (i) to provide that the risk of continuation of the pregnancy to the life of the woman should be "serious," and that injury to her physical or mental health should be "grave." He had the support of **Lord Parker of Waddington** on the ground that it would enable judges to direct a jury that it was not intended that it should be just "any" risk or slight injury but a serious risk and a real injury.

Lord Stonham, for the Home Office, pointed out that the British Medical Association and the Royal College of Obstetricians and Gynaecologists had said that these requirements could raise considerable difficulties in practice, and might mean that terminations carried out on certain medical indications that were accepted in current medical practice would become questionable in future. It was because of the strong representations of the responsible medical bodies that the words were taken out of the Bill in the Commons.

The amendments were withdrawn.

Health of Existing Children

The most contentious part of the discussion arose on an amendment moved by **Viscount Dilhorne** to leave out "any existing children of her family." The provision, he said, sought to introduce as a justification for abortion a criterion wholly unrelated to the condition of the pregnant woman. Let the test which the doctors could apply be a test of health in its widest sense, but let it be the health of the pregnant woman.

Lord Brock objected that the phrase departed from the medical considerations of abortion as they affected the physical or mental health of the woman. Where family background or circumstances were such as to prejudice her health the natural compassion of the doctor, fostered by his medical experience, would be sufficient to influence him to pay attention to these matters. But the phrase definitely introduced the problem of social reasons for abortion. It was the fear of many surgeons that they would then be called on to perform abortions for reasons not connected with the health of the pregnant woman herself. Some might be willing to do so for non-medical reasons, but most would not. It would not be right to expect a surgeon and his team to do something against their will and conviction.

Lord Platt said he could not support the amendment. The Bill, if passed into law, should be, with all proper safeguards, more permissive and not more restrictive than the present state of affairs. To rule out the words at this stage was almost tantamount to instructing doctors not to take account of the influence of social factors on the medical state of their patients and their patients' families. It would be a new and wholly undesirable departure from good doctoring.

Lord Molson, supporting Lord Silkin in the task of getting the Bill through, refused to accept the amendment. It had been made plain from the start that the supporters of this Bill were not satisfied that it should be merely a restatement of the doctrine in the Bourne case. It was intended to be a measure of social reform, and to go further than the existing law.

The amendment was carried, on a vote, by 87 to 86.

Conscience Clause

Lord Silkin moved to delete Clause 4 (conscientious objection to operation) and insert a redrafted clause (conscientious objection to participation in treatment). The new clause, which was agreed to, stated:

> (1) Subject to subsection (2) of this section, no person shall be under any duty, whether by contract or by any statutory or other legal requirement, to participate in any treatment authorized by this Act to which he has a conscientious objection:
>
> Provided that in any legal proceedings the burden of proof of conscientious objection shall rest on the person claiming to rely on it.
>
> (2) Nothing in subsection (1) of this section shall affect any duty to participate in treatment which is necessary to save the life or to prevent grave permanent injury to the physical or mental health of a pregnant woman.

Title of Bill

Lord Silkin moved an amendment to change the title to the Abortion Bill, by which, he said, it was known. The amendment was agreed.

He also proposed an amendment that the Bill should come into force six months after it was passed. This period was necessary, he explained, to enable the Ministry of Health to make the necessary preparations. The House accepted this amendment.

If Lord Silkin's fears are not realized, and the Bill is not lost in disagreement between the two Houses, it could obtain the Royal Assent at the end of October and come into operation next April.

S.T.P.

The current dispute on the effects of soft drugs in leading to addiction to hard drugs occupied the early attention of the House of Commons on 28 July, the day the House adjourned for the summer recess.

It was introduced by Mr. P. Channon (Southend, West, Con.), who asked the Government whether the subcommittee of the Advisory Committee on Drug Dependence, which is studying the question of soft drugs, would deal with cannabis.

Miss Alice Bacon, Minister of State at the Home Office, said that the Government was making urgent inquiries about S.T.P. It had not yet been placed under control in America, she said, and preliminary information suggested that its chemical structure would not bring it under British legislation. The Government Chemist was examining a tablet, and the Government was considering the need to bring it under control.

Cannabis was scheduled under the International Convention on Narcotic Drugs of 1961, to which Britain was a party. Since it was banned by virtually every country, it could not be freed from control without international consequences. It would be "entirely mad" for the Government to relax control over the drug without further information. Some 97% of all heroin addicts known to the Home Office had a previous history of taking cannabis.

The Minister stated that the number of convictions for the illegal use of cannabis was 554 in 1964 : 1,119 in 1966 ; and 530 in the first four months of this year.

Service Committees

Mr. G. Fowler (The Wrekin, Lab.) asked the Minister of Health how many cases were heard by National Health Service service committees in each year from 1960 to 1966, inclusive ; how many of these cases were the subject of a further appeal to the Minister or the tribunal ; and how many cases went in favour of the practitioner and how many in favour of the patient.

Mr. K. Robinson, replying on 19 July, stated that a number of the cases considered by service committees resulted from references by executive councils, not from complaints by or on behalf of patients, and separate figures for the latter type of complaint were not available before 1963. They were shown in brackets for 1963 and later years. Appeals were only to the Minister.

Year		Number of Cases	Appeals	Practitioner Found in Breach of his Terms of Service
1960	...	1,191	87	713
1961	...	1,341	95	744
1962	...	1,036	70	486
1963	...	1,086 (706)	94	463 (151)
1964	...	1,236 (836)	93	485 (149)
1965	...	1,159 (883)	95	413 (175)
1966	...	1,006 (738)	85	360 (151)

There were 552 service committees in England and Wales from 1960 to 1964. The number was reduced to 536 following a reduction in the number of executive councils on 1 April, 1965.

Air Pilots Certificates

Mr. Hector Monro (Dumfries, Con.) asked the President of the Board of Trade on 19 July for what reasons the medical examination for a private pilots' licence must in future be carried out by an authorized medical examiner and not by any medical practitioner.

Mr. J. P. W. Mallalieu, Minister of State: "It is desirable that medical certificates that give continuing validity to licences now issued for five years should be given by doctors who are knowledgeable about aviation medicine and the standards to be applied."

MEDICAL NEWS

Control of University Expenditure

In a statement in the Commons last week Mr. Anthony Crosland, Secretary of State for Education and Science, announced that the Government had accepted the Public Accounts Committee's recommendation that the Comptroller and Auditor General should be given access to the books and records of the University Grants Committee and the universities (see *B.M.J.*, 4 February, p. 251). The Government, he said, shared the view of the Committee that this item of Government expenditure, which had risen to well over £200m. a year, "can no longer continue to be the sole major exception to the normal requirements of Parliament regarding scrutiny and report." It would become a condition of grant to universities from 1 January 1968 that their books and records should be open to inspection.

Royal Society of Medicine

The following have been elected Honorary Fellows of the Royal Society of Medicine: Lord Cohen of Birkenhead, Mr. Cuthbert Dukes, Dr. Douglas Guthrie, Sir Robert Macintosh, and Professor Martin Rushton.

U.S. Honours British Dentists

On 27 July Mr. David Bruce, the United States Ambassador in London, presented the Elmer S. Best Memorial Award to Professor Martin Rushton, whose contributions to dentistry he described as "outstanding and of world renown." The award was established in 1961 by the Pierre Fauchard Academy of Cleveland, Ohio, in memory of its founder. Professor Rushton was educated at Cambridge University and Guy's Hospital, graduating in science, medicine, and dentistry. From 1959 to 1962 he was dean of the faculty of dental surgery at the Royal College of Surgeons of England. Other members of the dental profession who were honoured at the ceremony were Professor Bertram Cohen and Professor Bryan E. D. Cooke, who were presented with the honorary membership of the Academy.

Medical Computing Language

The Minister of Health, Mr. Kenneth Robinson, is setting up a committee to consider the need for a standard medical computing language. He has appointed as chairman Mr. D. White, an assistant secretary in the department who is in charge of computer policy and developments. Other members of the committee are: Professor J. Anderson, department of medicine, King's College Hospital ; Professor G. Black, National Computing Centre, Manchester ; Mr. R. A. Brooker, department of computation, Manchester University ; Dr. D. Michie, department of machine intelligence and perception, Edinburgh ; Dr. O. R. L. L. Plunkett, physician superintendent, St. Peter's Hospital, Chertsey ; Major J. B. Ready, medical records officer, Hospital for Sick Children, London ; Dr. B. Richards, department of computation, Manchester

University; and Dr. J. Scott, medical officer, University of Keele.

Education in Management

Wise management of existing hospital resources is the keynote of the annual report of King Edward's Hospital Fund for London. The Fund organizes courses in management for consultant medical staff and senior registrars. The main theme is the efficient use of resources (beds, services, money, and manpower) and ways and means of measuring efficiency. In September next year the four staff colleges will merge to form the King's Fund College of Hospital Management. Grants in 1966 totalled £239,768. About a third (£70,540) was devoted to research, much of it to practical studies designed to improve hospital service. A useful feature of the report is a summary of the Fund's activities in the form of annotated lists of grants, studies, and publications.

Changes in Trusteeship

The trustees of the Medical Commission on Accident Prevention have appointed Mr. Norman Capener, F.R.C.S., scientific director of the Commission, to succeed Sir Arthur Porritt when he resigns as chairman in September. Mr. Capener will be succeeded by Dr. C. A. Boucher. Copies of the annual report for 1966–7, recording the work of the various committees, can be obtained from the Commission's Executive Offices, 50 Old Brompton Road, London S.W.7, 5s. plus 6d. postage.

Courses for General Practitioners

A B.M.A. list of courses for general practitioners is now available. The courses referred to are being held from September to December and will last a week-end or one or two weeks. Copies of the list can be obtained on application to the Secretary, British Medical Association, B.M.A. House, Tavistock Square, London W.C.1.

People in the News

▶Lord Hill of Luton, chairman of the Independent Television Authority, is to become chairman of the B.B.C. Board of Governors.

News in Brief

On 26 July the Minister of Health, Mr. Kenneth Robinson, laid the foundation stone of the University Hospital of Wales and teaching centre at Heath, Cardiff. The building scheme is estimated to cost £19m.

The Department of Education and Science is seeking evidence of drug-taking by schoolchildren and students. It has written to chief education officers and principal school medical officers asking what steps are being taken to guard against this development and to ensure treatment for those who need it.

Grants and Awards

The Polar Medal has been awarded posthumously to Dr. J. K. Wilson, medical officer, British Antarctic Survey. (An obituary notice was published in the *B.M.J.*, 30 October 1965, p. 1067.)

Recent Publications

A report, *Pharmaceutical Research: The Case for Growth in Britain*, calls for an economic environment in which the industry can expand and compete internationally. Issued by the Office of Health Economics (162 Regent Street, London W.1).

Societies and Lectures

For attending lectures marked ● a fee is charged or a ticket is required. Applications should be made first to the institution concerned.

Wednesday, 9 August

Stoke Mandeville Hospital.—12.15 p.m., Mr. L. Cosin: New Thoughts on the Care of the Old.

Friday, 11 August

Institute of Diseases of the Chest.—5 p.m., Dr. H. Nicholson: clinical demonstration.

Universities and Colleges

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a quarterly meeting of the College held on 27 July, with the president, Sir Max Rosenheim, in the chair, Mr. D. H. Barran, chairman of the Shell Transport and Trading Co. Ltd., and Dr. J. A. P. Treasure, chairman of the J. Walter Thompson Co., were elected Friends of the College.

Sir John Richardson was elected representative of the College on the General Medical Council.

The appointment of Dr. D. E. Bedford as Harveian Orator and Dr. P. B. Beeson as Bradshaw Lecturer, both for the year 1968, was announced.

The following lecturers were also appointed for 1968: Lumleian Lecture, Dr. A. C. Dornhorst; Goulstonian Lecture, Dr. D. N. S. Kerr; Croonian Lecture, Dr. E. G. L. Bywaters; Bertram Louis Abrahams Lecture, Air Commodore H. L. Roxburgh; Humphry Davy Rolleston Lecture, Dr. Sheila P. V. Sherlock; Langdon-Brown Lecture, Dr. H. Harris. For 1969: FitzPatrick Lecture, Major General A. N. T. Meneces; Watson Smith Lecture, Dr. F. F. Hellier; Marc Daniels Lecture, Dr. W. R. S. Doll.

The Baly Medal was awarded to Dr. Bernard Katz.

The following Fellows of the College were elected Officers for the ensuing year: *Senior Vice-president*, Dr. Clifford Wilson; *Censors*, Dr. Clifford Wilson, Dr. N. S. Plummer, Dr. W. N. Mann, Dr. Cyril Astley Clarke; *Treasurer*, Dr. R. R. Bomford; *Registrar*, Dr. K. Robson.

At a meeting of the College held on 28 July the following, having satisfied the Censors' Board, were admitted members of the College:

A. R. M. A. Awwal, P. Beck, A. N. Bowden, R. L. Bown, C. G. D. Brook, A. S. Burney, J. H. Chamberlain, Mo Wah Chan, P. Cochrane, J. B. Cocking, J. J. Cogswell, P. Collins, Johanna A. Cotter, Gillian M. Craig, R. J. Cryer, D. R. Cullen, G. Danta, P. G. D'Arbela, Judith M. Darmady, J. R. E. Dathan, E. W. Davies, M. J. Dillon, B. O. L. Duke, A. L. W. F. Eddleston, Joy B. Edelman, P. C. Edmondson, C. F. Elliott, P. H. Q. Fernando, D. J. H. Fisher, F. V. Flynn, R. A. Fox, P. Ghosh, N. Gitlin, S. H. Green, Jacqueline Harris, R. Harris, D. R. Hart, P. Hillenbrand, K. Hollinrake, P. R. Hunter, A. F. M. A. Islam, U. S. Jayawickrama, M. B. S. Jones, A. B. Kay, N. Kesaree, A. M. S. I. Khan, M. Z. Khan, N. B. Kirkland, R. P. Knill-Jones, J. Knowelden, G. Lawton, A. W. Lees, A. R. Lo Su Fook, D. M. McCarthy, D. G. McCoy, G. McEnery, V. Mahadev, P. A. Majid, M. N. Marsh, J. S. Marshall, R. T. Maxwell, P. P. Meisner, W. R. J. Middleton, K. Miloszewski, C. M. Morgans, M. G. Moshal, P. Moulik, I. M. Murray-Lyon, J. M. Muscat-Baron, F. Navab, M. J. Noronha, M. D. O'Brien, M. C. L'E. Orme, R. C. L'E. Orme, B. C. Pakrashi, M. C. Pearson, Patricia M. Perera, M. C. Petch, J. M. E. Pinto, H. V. Price, D. J. Pugsley, J L. Quintner, K. W. Ranasinha, R. M. Rash, Margaret H. Retter, Mary A. Rossiter, A. H. Sabah, M. H. A. Sacoor, R. R. Shah, D. G. Shand, H. Shazli, Margot Shiner, B. R. Silk, P. Singh, A. S. Sinnatamby, P. H. Smith, C. J. F. Spry, The Honourable Trevor C. B. Stamp, Sabina T. Strich, R. O. C. Summers, P. K. Talukdar, D. R. Thomas, D. A. Toms, B. K. Toone, Joan M. Trowell, Po Yiu Tso, D. S. Tunstall Pedoe, H. D. Tunstall Pedoe, Sheila L. Waller D. C. Webb-Johnson, G. H. Whitehouse, J. A. Whittaker, S. P. Wickremasinghe, A. Wilson, H. I. Winner, R. C. Wofinden, J. K. Young.

Diplomas

The following diplomas were granted, jointly with the Royal College of Surgeons of England:

Diploma in Child Health.—R. G. Wilson.

Diploma in Industrial Health.—D. M. Davies, M. Y. El-Tonbary, J. H. Elwood, W. R. Esson, J. S. Hall, R. A. Mahmoud, S. P. Mukherjee, El S. M. Saad, F. Sattarzadeh, A. A. Tehranian, A. Vassigh.

Diploma in Laryngology and Otology.—G. R. Gokani, S. Hussain, Y. A. Ismail, Ikram-Ullah Khan, I. Z. Khan, J. McNeill, S. N. Mukherjee. H. E. Porte, P. B. Rajput, T. M. S. Saluja, A. N. Samanta, S. M. S. Senanayake, M. S. A. F. Sheta, N. K. R. Shetty, M. P. Thomson, Eileen J. Vega, F. G. Youssef.

Diploma in Medical Radiodiagnosis.—A. V. Mitchell, A. K. Bose.

Diploma in Ophthalmology.—Margaret H. Brennan.

Diploma in Psychological Medicine.—J. C. Ague, A. Ahad, S. A. Ahmed, S. Bal, R. N. Bale, O. Ben-Arie, Sylvia M. Blunden, R. K. Brahma, P. Busapathumrong, J. J. Byng-Hall, W. H. K. Carpenter, M. Chandra, Evelyn M. Cheongvee, R. S. Curnow, C. J. David, P. Dening-Smitherman, N. Destro, W. Dunn, Janet Y. Eccles, D. J. P. Ellis, D. P. Eyre, I. Freedman, J. B. Frost, A. S. R. Goonetilleke, G. W. Goulden, Joyce Gunawardena, Elizabeth J. Harbott, P. W. E. Hayward, D. W. Hill, G. T. Hollingworth, H. Hpay, D. S. James, Annabel M. Jenkins, M. E. D. Johns, A. M. Jukes, C. H. Kelland, J. A. Kohiyar, O. Kyaw, A. Shiu-Hung Leung, Yolande Lucire, N. C. MacKenzie, R. S. Mackinnon, A. L. McKnight, J. E. Miles, N. Mohit-Mafi, A. B. K. Morrall, Elizabeth McQ. D. O'Brien, E. G. Ostler, R. S. Parmar, S. J. Parthev, S. W. Pendaeli, Gwenllian J. Pryce, Ann Rhys, Nancy M. E. Robertshaw, A. H. Robbins, G. Sakalis, Noeline P. Sebaratnam, U. P. Seidel, D. M. Shaw, Margaret R. Sheridan, Nancy K. Shrubshall, G. J. S. Simpson, Ann C. Spark, T. G. Tennent, E. B. Tompkins, P. M. J. Walsh, R. M. C. Welldon, Joy E. West.

Diploma in Public Health.—V. B. G. Amu, S. Datta, Lillian K. L. Lim, A. W. C. Lobban, June D. Mills, Uma K. Nathwani, K. V. Shah, A. K. B. Svindland, D. P. Upadhya, Elsie L. M. Wallace, G. E. P. Williams.

Corrections

In the leading article on the "Changed Character of Osteomyelitis" (29 July, p. 255), Dr. L. R. I. Baker and his colleagues were said to have reported that "other debilitating diseases such as neutropenia secondary to systemic corticosteroid therapy" might precipitate osteomyelitis. This should have read "rare precipitating causes include systemic corticosteroid therapy and hypogammaglobulinaemia, and debilitating diseases such as neutropenia as recently reported by Dr. L. R. I. Baker and his colleagues."

Drs. E. C. Hutchinson and A. J. McCall write: We regret that there is an omission in the summary of our paper on "Stenosis and Occlusion of Vessels in Cerebral Infarction" (29 July, p. 270). The summary refers only to "Occlusion of the cerebral arteries" and should have read: "Occlusion of cerebral, carotid, or vertebral arteries was found only in the infarct group and the incidence of stenosis in this group is significantly higher than in the controls."

All communications with regard to editorial business should be addressed to The EDITOR. British Medical Journal, B.M.A. House, Tavistock Square, London W.C.1. Telephone: 01-387 4499. Telegrams: *Aitiology, London W.C.1.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs.

ADVERTISEMENT AND SUBSCRIPTION ORDERS should be addressed to The Manager at B.M.A. House, London, or at 415 Bourke Street, Melbourne, Victoria, Australia.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the British Medical Association, B.M.A. House, London, or to the Scottish Secretary, B.M.A. Scottish Office, Drumsheugh Gardens, Edinburgh.

Future of General Practice

Perhaps the holiday season brought relaxation to the General Medical Services Committee's discussion (reported in the *Supplement*) on the future of general practice, or perhaps a fear, voiced by more than one speaker, of the demise of this branch of medicine served wonderfully to concentrate the Committee's mind. Whichever it was, the subject had a good going over. That no definite conclusions were reached is relatively unimportant. What matters is that in holding the debate the Committee showed that it is getting its priorities right.

General practice has been examined often enough—some would say too often. Certainly too much scrutiny may have aggravated in it a tendency to neurosis if not to hypochondria. In such cases one opinion after another is commonly sought. Had the National Health Service not intervened individual general practitioners over the past 19 years would have had to work out their own salvation. Left to themselves it may be assumed that most, out of sheer necessity if for no other reason, would have made their practices efficient. It will never be known how they would have compared with what exists today. But it can be said that the nationalized medical service, in which individual action is governed largely by collective decisions, has been singularly ineffectual in equipping general practice for a modern role.

The G.M.S. Committee is the recognized spokesman for general practitioners and it voices the profession's views on general practice—two functions that are not always the same. If in the past the Committee has spoken more loudly for general practitioners it was doing what was expected of it by doctors whose professional way of life had been revolutionized and whose livelihood had become dependent almost wholly on the State as a monopoly employer. It took threats of resignation, an arbitration, a royal commission, and the setting up of a special body to review doctors' pay to instil into successive Ministers of Health and their administrations some idea of their responsibilities towards their medical employees. The publicity surrounding these disputes did nothing to enhance the reputation of either side. And neither the Government nor the profession foresaw the intolerable strains that a free medical service available to all on demand was bound to exert on doctors under contract to provide it. New terms and conditions of service for family doctors have now been agreed which, if they are not the final answer, at least dispose of the worst features of the old. General practitioners can now more freely turn their attention to promoting the much-needed reforms in the organization of their work—a pursuit that will enlist the sympathy of the public.

General practice in the future must be such that it can offer keen doctors well trained in medicine a continuing opportunity to practise and to improve their skills. Only when general practitioners can get back into the stream of medicine will they regain their confidence and their branch of practice its prestige. The basic requirements for these are

© *British Medical Journal*, 1967. All reproduction rights reserved.

clear, even if the ways for getting them are not. Firstly, general practitioners must have a sound knowledge of medicine. Secondly, the conditions in which they practise must be such that they can apply their knowledge to the full. Thirdly, they must have time for unhurried clinical work. Fourthly, they must have time to keep up to date. Fifthly, their pay must be enough to ensure for them a fair standard of living. Doctors must in the main learn as they earn, and there is no greater stimulus to keeping abreast than working alongside colleagues in the same and in other branches of medicine. The trend must be towards practice in groups and closer association with hospitals. It is for consideration whether that might lead naturally to a unified medical service based on hospitals and with a common career structure for doctors.

Fears that in the demand for greater efficiency in medical practice the more human needs of the patient may be forgotten are not groundless. One of the finest features of British general practice is the admirable relationships which have bound doctors and patients together. Some of the art in medicine, so essential when science was lacking, is outworn. But modern medicine takes patients as well as doctors anxiously into unfamiliar ground. If courtesy, kindness, and gentleness form part of the art of applied medicine then there will be more need than ever in the future for the exercise of these qualities in the doctor–patient relationship. It is never out of time for doctors to remind themselves that if one of their prime duties is to cure when possible so it is also to comfort always.

Penicillin Encephalopathy

Not long after penicillin first became available it was realized that it could cause epileptic fits if injected directly into the brain or if too concentrated a solution was introduced into the ventricles or the subarachnoid space.[1] [2] This led to the use of diluted solutions in the intrathecal treatment of, for instance, pneumococcal meningitis. And despite long-term treatment in high dosage given by mouth or intramuscular injection to thousands of patients toxic effects on the nervous system have been rare. They have included occasional hypersensitivity reactions and the disastrous results of direct injection into a nerve trunk. The protective action of the blood–brain barrier and the efficiency of clearance mechanisms no doubt prevent toxic levels being reached in or around the nervous tissue. However, if either or both of these mechanisms break down, and if in addition the penicillin is given intravenously in very high dosage, as in the treatment of some relatively resistant Gram-negative organisms, then a much more dangerous situation may arise.

Since 1952 nine cases have been reported of an encephalopathy developing under such circumstances, and H. A. Bloomer, L. J. Barton, and R. K. Maddock[3] have now added four of their own. By describing these in conjunction with six of the previously reported cases they have built up a remarkably uniform clinical picture. All the patients except one were in their sixth to eighth decade, and all had renal insufficiency at the time of the onset of toxic symptoms. Penicillin was being administered intravenously for infections with resistant Gram-negative organisms in a dosage amounting to at least 25 million units per day, and often considerably more. After two to three days the patients' conscious level became depressed, some becoming comatose, and this was rapidly followed by myoclonic jerking, affecting particularly the face, pectoral muscles, and limbs. The jerks were at one time focal, at another generalized, sometimes occurring in bouts resembling a status epilepticus. In between these bouts some patients were able to communicate normally, but in others generalized convulsions also occurred. Phenobarbitone gave little benefit, but liberal and repeated use of paraldehyde controlled the myoclonus. In seven patients on discontinuing the penicillin the syndrome settled down, but coma persisted in the remaining three and death ensued. Few of these patients had any history of disease affecting the central nervous system, and they were not overhydrated, hypertensive, or suffering from electrolyte disturbance. The same authors refer to a similar syndrome, developing under similar circumstances, in a uraemic patient on intravenous sodium cephalothin and point out that renal failure potentiates the toxic effects of chloramphenicol, streptomycin, and polymyxin.

Clearly it is necessary to bear in mind the danger to the nervous and vestibular system of antibiotics given intravenously in high dosage to patients in renal failure, a point emphasized only a few weeks ago in this journal by the studies of J. R. Curtis, S. J. McDonald, and J. H. Weston[4] on the use of gentamicin. Indeed the symptoms may be mistaken for uraemic convulsions rather than for an effect of the treatment. For such patients it is possible that bactericidal levels of the antibiotic may be obtained on lower dosage and with less danger to the nervous system. And if, as it seems, penicillin G is particularly apt to produce such an encephalopathy, other antibiotics might be considered as first choice in treatment. When a preparation is as safe as penicillin there is a danger of becoming a little careless about its use, and this recent study sounds a timely note of warning.

Rheumatic Fever in Scotland

In 1939 2.6% of London schoolchildren under 15 years of age had had rheumatic fever,[1] though its incidence had been falling for many years. The crude annual death rate from rheumatic fever in England and Wales was 67 per million living in 1901, 23 per million in 1939, and 2 per million in 1965.[2] [3] The fall continues, but the disease still presents important problems, for its victims are mainly children and young adults, and with proper application of our present knowledge it could be largely eliminated. In addition, though new cases are now uncommon, there are still a large number of patients with heart disease resulting from rheumatic fever.

In 1962 the Standing Medical Advisory Committee of the Scottish Health Services Council appointed a subcommittee "to consider the problem of rheumatic fever and rheumatic heart disease in Scotland with particular reference to the incidence of these diseases and the means of prevention." Its report,[4] recently published, gives the facts in Scotland, largely from the mortality returns of the Registrar General for Scotland and the morbidity statistics of the Scottish regional hospital boards and school medical service. A special survey of schoolchildren was attempted but proved unfruitful and was abandoned.

Deaths from rheumatic fever in Scotland fell from 0.9 per 100,000 living in 1953 to 0.3 in 1962 and 0.1 in 1963. The 1962 figure is comparable with that in many "developed" countries—for example, England and Wales, Australia, and the United States. By contrast the figure for Northern Ireland is 1.8. Deaths from chronic rheumatic heart disease show the expected preponderance of females. Scotland had 19.2 per 100,000 deaths of females and 9.5 per 100,000 deaths of males from chronic rheumatic heart disease in 1962, a slight drop from the 1953 figure. The English figures are about the same as the Scottish, in fact slightly higher, but those for Northern Ireland are distinctly lower. Most of the deaths still occurring were of people in the latter half of life. The classical relation between rheumatic fever and poverty, probably overcrowding, is shown by the relatively high frequencies in the Glasgow and Lanarkshire areas.

School medical examinations showed a fall in the incidence of acquired organic heart disease (synonymous with rheumatic heart disease at that age) from 361 per 100,000 examined in 1949 to 95 in 1964. By contrast the incidence of congenital heart disease rose over the same period from 221 per 100,000 to 376. The report ascribes this to greater interest in and better diagnosis and treatment of congenital heart disease in recent years. This is probably true, though difficult to assess quantitatively. Experience with rubella and more recently with thalidomide should warn us of the danger of regarding all congenital anomalies as genetically caused.

In their recommendations on means of prevention the authors of the report advise chemoprophylaxis,[5] the reduction of overcrowding, and the further use of questionaries by the school medical service. The value of chemoprophylaxis is well documented. It is disappointing that the committee did not take the opportunity to find out why it is not more used. Is it lack of information or of enthusiasm by those who should be prescribing it? Or is it fear of producing penicillin-resistant strains of bacteria? Penicillin-resistant β haemolytic streptococci have not been reported in children on prophylactic penicillin,[6] but resistant *Streptococcus viridans* organisms have. Thus subacute bacterial endocarditis with the resistant organisms is a rare possibility.[7] It would also have been interesting to discover to what extent the chemoprophylaxis already prescribed was being actually taken, for reluctance to receive prolonged undramatic prophylaxis may have to be overcome.[8]

Trousseau wrote[9]: "So distinctively characterized a disease as rheumatism ought to have only one remedy; but no such specific is within our reach." We still have no remedy, but prophylactic measures deserve more attention.

Experiments on Man

Traditionally British institutions have tried to meet problems as they arise rather than legislate for them in advance. Thus medical institutions have never sought to lay down hard and fast rules of ethical conduct for research projects on man. True, valuable guidance has been forthcoming from both the Medical Research Council[1] and the World Medical Association,[2] but the final responsibility has always been held to rest squarely on the individual worker undertaking the research. Recently, however, some medical men have claimed that this practice, in Britain and elsewhere, does too little to safeguard the patient's interests, and that stricter controls are necessary.

The U.S. Public Health Service has already acted.[3] Since November it has declined to support investigations unless they have first been approved by a professional committee of the institution concerned. Subsequently the committee continues its scrutiny of the project and gives advice to the research workers. In a lecture in London on human experimentation Professor W. B. Bean,[4] of Iowa, proposed that any research project should be assessed by a group of the doctor's peers, though he insisted that legislation was undesirable. And M. H. Pappworth[5] has suggested that consultation committees should be formed for each large hospital or hospital group, and that these in their turn would be responsible to the General Medical Council and to Parliament.

It is against this background that a recent report by a special committee of the Royal College of Physicians (p. 429) must be viewed. It divides "clinical investigations" into those with diagnostic or therapeutic relevance and those from which the subject cannot expect direct personal benefit. Like previous commentators, the College sees the second as the type more likely to present ethical difficulties. Formal codes, it states, can provide only general guidance, and their application to particular problems is often a matter of opinion. The report rightly rejects rigid or central bureaucratic controls, because these would deter doctors from undertaking research and retard the growth of medical knowledge. Like the U.S. Public Health Service, the College is in favour of scrutiny by committee, proposing that in any institution in which clinical investigations are done a group of doctors should satisfy itself that a project is ethical.

Obviously some kind of guidance should be welcomed by the research worker who is inexperienced or in genuine doubt about the issues concerned. The right of consultation among colleagues is one of the most prized possessions of the professional man. Scrutiny by committee might well prove to be a valuable complement to the statements by the M.R.C. and the W.M.A. But today there must be relatively few research projects which are not first extensively discussed with fellow workers. It is questionable whether the more difficult, basic problems can be solved by a committee—particularly a committee having the deliberately vague terms of reference laid down by the Royal College. Such a system will not deter the very person at whom it is aimed—the man determined to finish a project unrestrained by any scruples. But it could cause appreciable delay to workers whose ethical integrity cannot be questioned. Furthermore, the mere creation of a committee will do little to satisfy those laymen or medical men who have called for more far-reaching action.

[6] Biörck, G., *Brit. med. J.*, 1965, **2**, 7.

Two years ago, surveying the next ten years in medicine, Professor Gunnar Biörck[6] prophesied the probable decline of the importance of the individual at all levels—what he termed a change from the "individual-centred" attitude to the "group-centred" one. Some might feel that the College's proposals are a step in that direction. Whatever the system for supervising the ethical aspects of research the ultimate safeguard must be the conscience of the individual worker. Medical teachers have a prime responsibility to instil this into their students and junior staff, particularly by their example. Medical journals can also play a part by refusing to publish papers when the propriety of the work is questionable. It is important, too, that the issues should be publicly and constantly debated. But in the final reckoning the decision about a particular project is one for the doctor concerned, and for him alone.

New Light on Leprosy

Leprosy constitutes one of the biggest health problems in the world, and probably about four million patients in tropical Africa and three million in the Indian subcontinent are suffering from the disease. It is an uncommon condition in Britain and only about 50 new cases are notified each year. Though the acid-fast organisms discovered by Hansen in 1872 were the first bacteria to be aetiologically associated with human disease, scientific proof that *Mycobacterium leprae* is the cause of leprosy is still lacking because Koch's postulates have not yet been fulfilled. Despite numerous attempts by successive generations of research workers the organism has still not been grown in vitro.

In 1960 C. C. Shepard[1] inoculated nasal washings from lepromatous patients with highly positive smears into the footpads of mice and succeeded in producing limited multiplication of *Myco. leprae*. Shepard's results were confirmed and extended by R. J. W. Rees[2] as well as by other workers, and for the first time a technique was available to test antileprosy drugs in animals and to confirm cases of presumed resistance to dapsone.[3] Unfortunately this experimentally produced infection remained localized and multiplication of bacilli occurred only on a small scale; moreover, the histological appearance of the lesions produced was different from that seen in patients with leprosy and the animals suffered no general reaction to the disease.

There are two well-defined forms of leprosy: firstly, diffuse lepromatous leprosy, characterized by unrestrained multiplication of *Myco. leprae*; and, secondly, self-healing tuberculoid leprosy in which few bacilli are present. These differing patterns are probably the result of little-understood differences in the patient's immunological state; indeed, little is known also about the interplay of humoral, cellular, genetic, and other factors in leprosy. Since Shepard's pioneer experiments numerous other attempts to reproduce the disease in animals have been made with varying success, the ultimate object being to achieve progressive infection with systemic dissemination and the production of lesions resembling the disease in man.

Recently Rees and his colleagues[4] have succeeded in reproducing in mice a picture very similar to the human disease. The immunological capacity of these animals was reduced by a combination of thymectomy and total body irradiation before they received injections of leprosy bacilli. Rees and his colleagues describe four main findings. Firstly, there was an appreciably higher yield of bacilli from the footpads and ears of the mice, compared with the untreated animals. Secondly, a year after inoculation dissemination of the initial local lesion had occurred. Furthermore, the infected footpads in some of the animals had become swollen, and the overlying skin was covered with small nodules. Thirdly, the histological picture in the ears, footpads, and cutaneous nerves was comparable with that in skin and cutaneous nerves of patients with lepromatous leprosy. Lastly, intravenous injection of a suspension of bacilli produced for the first time a systemic infection in the ears and footpads of the mice.

These results represent a substantial advance in the experimental study of leprosy, and further progress in this field will be awaited with interest.

Psychogenic Vomiting

There are many causes of vomiting, itself a common disorder. And because the metabolic effects of depletion of water, electrolytes, and calories may have serious consequences for the patient, it is essential if the cause is not obvious after a complete clinical examination to proceed to full biochemical and radiological investigation.

Exclusion of pyloric and small bowel disease is most important, and this is aided by *x*-ray examination. Gastric lavage is an important preliminary to this, because as well as lessening the risk of vomiting during the examination it allows better visualization with a small amount of contrast material—an important factor if subsequent surgery is required. Toxic causes, such as those associated with uraemia, cortisol deficiency, and hypercalcaemia are usually discovered as a result of determination of serum and urinary electrolytes, blood urea, and blood 11-hydroxy-corticosteroids. The group of cases associated with raised intracranial pressure or lesions of the inner ear and brain stem are not usually misdiagnosed because of the other symptoms which accompany the vomiting—for example, headache, tinnitus, and vertigo—and of the physical signs these disorders produce.

Though many conditions are quickly diagnosed, there are some patients, particularly those with chronic vomiting over a number of years, in whom an adequate diagnosis is never made; the vomiting is then usually labelled "functional." Patients in whom this diagnosis is made are either given sedative drugs or drugs aimed at preventing vomiting, or conveniently a phenothiazine preparation with both properties. It is popularly believed these people do not as a rule develop any of the complications, such as dehydration or hypokalaemia, seen in those with organic vomiting.

According to O. Hill[1] the concept of the psychogenic vomiter remaining in reasonably good health is not always true. He gives examples of severe potassium depletion leading to paralysis of voluntary and smooth muscles in three patients with psychogenic vomiting, and stresses that the paralysis may be considered hysterical unless studies of potassium metabolism are made. A low serum level of potassium, a raised alkaline reserve, and a raised blood *p*H usually substantiate the diagnosis of chronic potassium deficiency. The finding of a low urinary level of potassium excretion, provided the patient does not have renal tubular disease, and of electrocardiographic changes (ST depression and U waves) are further supporting evidence of this state, and a dramatic response to potassium supplements completes the diagnostic picture.

---

[1] Hill, O. W., *Gut*, 1967, **8**, 98.

Patients with psychogenic vomiting are more commonly female than male, and the history may date back to childhood. Psychiatric problems may not be obvious unless a long and exhaustive history is taken, and patients with this disorder will admit to their difficulties only if their problems are sympathetically and carefully handled. A carefully taken history will often disclose conflicts at home and in particular an unhappy relationship with parent or spouse. Hill records that during one interview one of his patients was " overcome by nausea " when the interviewer mentioned the particular member of the family with whom the patient was in conflict. Such a spot diagnosis from the history stresses the important factor that the answer lies in the patient's story. The well-worn phrase " You make me sick " really does have a meaning, for vomiting is a physical expression of unhappiness in a disturbed family environment.

We are used to functional diarrhoea and abdominal pain, functional loss of weight, and anorexia seen at its most extreme in anorexia nervosa. Likewise, functional vomiting can be diagnosed in some cases. Potassium supplements and psychiatric help may bring good health to these troubled patients once organic disease has been excluded.

Ruptured Chordae Tendineae

Chordae tendineae tether the fine edges of the mitral valve cusps to the papillary muscles. Rupture of them presents a syndrome that is being distinguished with increasing accuracy from that of chronic rheumatic mitral insufficiency. Accurate diagnosis is important because the prognosis, indications for surgery, and surgical management of the two are different.

This condition may complicate mild rheumatic insufficiency or may arise in a previously normal heart. The exact mechanism that causes a chorda to rupture is usually not obvious,[1] but subacute bacterial endocarditis and trauma may sometimes be implicated. Myocardial infarction affecting the posterior papillary muscle causes a similar picture to that of rupture of chordae tendineae.[2]

Either or both of the mitral valve cusps may be left unsupported by the ruptured chordae. The centre of the cusp becomes flail and forms a hood that balloons back into the left atrium in systole. In the case of the posterior cusp a jet of blood is directed forwards against the atrial septum and root of the aorta, while in the case of the anterior cusp it is directed backwards.[3] The haemodynamic disturbance is therefore one of acute and severe mitral incompetence in a previously normal or nearly normal heart. The left atrium is small and uncompliant, and the giant " v " wave in systole is transmitted directly to the pulmonary capillaries.

The clinical picture is characterized by the early onset of severe and progressive effort dyspnoea, often with attacks of pulmonary oedema. The physical signs are those of severe mitral insufficiency, but in contrast with chronic rheumatic mitral disease the patient is usually in sinus rhythm, and the pansystolic murmur has a mid-systolic accentuation. The anteriorly directed jet associated with a flail posterior cusp causes radiation of the murmur to the aortic area and carotid arteries, which, combined with the " diamond " shape of the murmur's distribution, may give rise to confusion with aortic valve disease.[3]

The chest radiograph shows the small heart and left atrium and cardiac catheterization the huge " v " wave in the left atrium. An only slightly raised end-diastolic pressure in the left ventricle suggests that the ventricle has not been significantly affected by rheumatic fever or subjected to a long-standing volume overload. Injection of contrast medium into the ventricle confirms the severity of the mitral incompetence but seldom shows the exact valvular lesion.

The prognosis is poor, and, again unlike chronic rheumatic mitral disease, the downhill course rapid. If medical treatment fails to relieve incapacitating symptoms surgery is advisable. Recommendation of surgical treatment is made more readily than in rheumatic disease because the lesion can often be cured without having to use a prosthetic valve, the long-term endurance of which is not yet established.

The operative techniques available are basically of three types—replacement of the entire valve with a prosthesis,[2 4] the formation of artificial chordae from prosthetic material,[5] and plication of the flail cusp so that it becomes supported by the remaining chordae (the McGoon procedure).[6] The substitution of artificial chordae has been almost uniformly unsuccessful because of late recurrence of incompetence,[4] which has left surgical practice divided into two schools. One recommends prosthetic valve replacement in every case, and the other finds the McGoon plication operation satisfactory in both the short and long term. There is no doubt now that the latter is correct, particularly when the posterior leaflet is involved. The surgical results of both procedures are considerably better than those for chronic rheumatic mitral disease, probably because the left ventricle is in much better condition.

Hirsuties

Hirsuties may be defined as an excessive growth of body hair, or hair at body sites other than those of the head, the pubis, and the axillae. The definition is also conventionally restricted to its appearance in women.

One question immediately raised by this definition is, " What is an excessive growth of hair ? " The growth of hair on the body is a graded characteristic, and its degree varies widely among individuals. Moreover, while the amount of growth is generally greater in men than in women, some overlap between the sexes does occur.[1] Theoretically, therefore, it might seem difficult to draw a line between normal and excessive hair growth—though in clinical practice this is not usually a real problem.

[4] Sanders, C. A., Austen, W. G., Harthorne, J. W., Dinsmore, R. E., and Scannell, J. G., *New Engl. J. Med.*, 1967, **276**, 943.

[5] Morris, J. D., Penner, D. A., and Brandt, R. L., *J. thorac. cardiovasc. Surg.*, 1964, **48**, 772.

[6] McGoon, D. C., ibid., 1960, **39**, 357.

Two factors appear to be concerned in the degree of hair growth. One is hormonal, probably related to the amount of circulating androgen. The marked differences in the amount of hair found at various sites of body hair suggests that sensitivity to the action of circulating androgen plays a part in this distribution. The nature of the circulating androgen has been the subject of considerable speculation. Testosterone was an obvious explanation of hair growth in man, but some other explanation had to be found in women. Though some androgenic compounds are secreted by the adrenal gland, with the possible exception of androstenedione they are weakly androgenic, and it seemed doubtful whether they would explain excessive growth of body hair in women.[2] Pointing out that testosterone was much the most potent androgen known, R. I. Dorfman[3] suggested that amounts circulating in the blood undetectable by methods previously available would be enough to cause growth of body hair in women. Subsequently, using a highly sensitive method M. Finkelstein and his colleagues[4] were able to demonstrate that a small amount of testosterone is present in the plasma of women. This was quickly confirmed by a number of other workers, and many authorities now appear to accept testosterone as the physiological androgen in both sexes. The precise site of origin in women remains uncertain. There is evidence for its production by the ovary and the adrenal, and for its production from other androgenic compounds after secretion into the blood stream.

The other factor in hirsuties is constitutional, affected subjects representing one end of a biological range. All other causes of the condition are unusual. They include corticotrophin-producing tumours of the pituitary, congenital adrenal hyperplasia (including a form that first manifests itself at puberty), bilateral adrenal hyperplasia of later life, tumours of the adrenal cortex, various masculinizing tumours of the ovary (including arrhenoblastoma, Leydig, and hilus cell tumours, and the rare hilus-cell hyperplasia[5]), and finally iatrogenic hirsutism produced by giving androgenic compounds in therapy. Nevertheless, hirsuties in much the largest group of patients is of unknown aetiology. No clear-cut biochemical abnormality is demonstrable, though there is indirect evidence that testosterone production is above normal.[2]

Differential diagnosis can be difficult and require specialist assessment. Clinically, age may be an important pointer; thus excess hair appearing at puberty and in the 'teens is likely to be constitutional in origin; appearing in childhood or later life it is probably due to other causes. Pituitary and adrenal causes are usually, though not invariably, associated with a raised excretion of 17-oxosteroids. Pregnanetriol excretion is increased in some forms of congenital adrenal hyperplasia. Normal levels of 17-oxosteroid excretion are found in ovarian forms of hirsutism.

Treatment of the constitutional type of hirsutism is essentially cosmetic, the administration of hormones being ineffective. Shaving, plucking, depilatory creams, removal by wax, and bleaching—all have a role in treatment, though none of them can produce permanent improvement. The most effective and permanent relief is obtained by electrolysis—but this is tedious, time-consuming, and expensive, and it is usually reserved for treatment of the beard area.

Blood Changes in Manned Space Flights

When we see pictures of astronauts preparing to take their part in manned space flights the "medical check" always features prominently. We know too from the daily press that elaborate medical and physiological checks are carried out when the astronauts return to earth. But the results of all this work have hardly been made known at all to the general medical reader. Now C. L. Fischer, P. C. Johnson, and C. A. Berry have published[1] an account of the changes they have detected in red cell mass and plasma volume in the astronauts manning three Gemini space flights. The three flights differed in length: the Gemini IV flight lasted some 97 hours, Gemini V 191 hours, and the Gemini VII flight, which was most extensively studied, lasted 330 hours. In the shortest flight plasma volumes were measured before and after flight, in the 191-hour flight plasma volumes and red cell mass were determined, and in the longest flight these measurements and the survival of red cells, as estimated by the radio-chromium test, were determined.

The results are interesting even if the data were, in the authors' opinion, not as complete as could be wished. "Because of the problems of scheduling, and the safety requirement that no blood be drawn from the astronauts for three days prior to lift-off, all venepunctures were kept to a minimum. The blood studies on recovery were accomplished with makeshift facilities on the recovery aircraft-carriers. The radioisotope studies were only a small part of the demands on the astronauts' time. This precluded the use of more refined techniques and drawing more frequent blood specimens to obtain die-away plots of injected radioactivity for estimation of erythrocyte survival." With these very understandable limitations they were able to show that in the Gemini IV and V flights there was a decrease of plasma volume of the same order as would be expected from similar periods of bed rest. In one of the Gemini VII astronauts, however, the plasma volume actually rose. This may be because the conditions of flight were different, for the Gemini VII astronauts were not only in space for a longer period but also spent some days out of their space suits. The red cell masses also decreased during the period of flight by amounts varying from 7 to 20%. The values returned to normal later; in the Gemini VII crew this took three weeks.

But the most interesting finding is that there was a mild but definite increase of red cell destruction in the crews of the Gemini V craft and in one of the crew of the Gemini VII craft. This mild haemolysis appeared not to be compensated for by an increase in red cell production during the period of the flight. After the flight findings returned to normal in about three weeks. The cause of this mild haemolysis is so far not determined, but it will be studied further, because clearly in long flights such an effect might become important. The detailed data about these results have been described in published reports of the proceedings of conferences held after the flights. Perhaps we can now expect further summary reports of the results of the medical and physiological studies that are of interest to the medical profession everywhere.

Autistic Conditions in Early Childhood: A Survey in Middlesex

J. K. WING,* M.D., PH.D., D.P.M.; N. O'CONNOR,* M.A., PH.D.; V. LOTTER,* PH.D.

Brit. med. J., 1967, 3, 389–392

Kanner (1943, 1957) was the first to point out that one particular syndrome of abnormal behaviour could be separated from the previously undifferentiated group of childhood psychoses. Children with the syndrome (called early infantile autism) were distinguished by three outstanding characteristics: lack of responsiveness to other human beings—that is, "autism"—an insistence on the preservation of sameness in the environment, and an onset in the first two years of life. The children were attractive and alert in appearance, and Kanner believed they were not intellectually subnormal, though their functional abilities were grossly impaired. Their parents in most cases seemed vocationally successful and intelligent.

In retrospect the syndrome had already been brilliantly described by Itard, whose account of the "Wild Boy of Aveyron," written in the early years of the nineteenth century, has never been bettered (Humphrey, 1932). Itard did not agree with Pinel's diagnosis of severe subnormality and evolved an educational technique which is now being rediscovered by psychologists (Lovaas, 1966).

Subsequent writers have not been able to improve upon Kanner's clinical acumen. The best recent descriptions, unmarred by interpretations of what might or might not be going on in the child's mind, are by Rutter (1966a) and Wolff and Chess (1964, 1965). These writers, as well as Creak and Ini (1960), confirmed certain of Kanner's findings, but in children in whom onset was sometimes later than the age of 2 years. Like Kanner, Rutter and Wolff and Chess emphasize the importance of the speech disorder, which in many cases seems impossible to differentiate from the receptive type of developmental aphasia (Pronovost *et al.*, 1966). In Creak's (1963) and in Rutter's (1966b) series, followed up into late adolescence or adulthood, there was no evidence of any development into schizophrenia. Kanner has also pointed out the lack of genetic relationship between schizophrenia and early infantile autism.

No epidemiological study has been made and the prevalence of the condition is unknown. The present survey was undertaken at the suggestion of Dr. Guy Wigley, then Medical Officer of Health for Middlesex and now Deputy Medical Adviser to the Greater London Council. Funds were generously provided by the Middlesex County Council.

Terminology

The term "autistic" can reasonably be applied, descriptively, to a much wider range of conditions than those included in the present series, just as this series contains some children without an onset in early infancy and some who had evidence of gross organic illness. No doubt, eventually, a more exact terminology will be possible which differentiates groups of children. All we can do at this stage is to describe as precisely as possible the basis for selection of a series and to assign a name arbitrarily. The term "autistic condition of early childhood" is used in this article to emphasize that, in addition to those with Kanner's syndrome, some children have been included who showed characteristics which Kanner might have considered a basis for exclusion (notably, an onset between 2 and 5 years, and the presence of gross organic features). However, the other substantial group of conditions, also sometimes called "autistic," in which the main symptom is social withdrawal, in the absence of the central features described here, has been excluded from this series and our conclusions do not refer to them.

Aims and Method

The major aims of the survey were to estimate the prevalence of "autistic conditions in early childhood" in Middlesex and to investigate certain assumptions which had been made about the male : female ratio, birth order, parental occupation and intelligence, and the prevalence of mental disorder in close relatives.

The method has been described in detail by Lotter (1966a). Briefly, the whole population of Middlesex aged 8, 9, or 10 on 1 January 1964 (78,000) was screened by means of a specially developed behavioural questionary based on an amplified and modified version of the Creak Committee's "Nine Points" (Creak *et al.*, 1961). This was completed by school-teachers, occupation centre supervisors, nurses, or parents. Only 1% of the population at risk could not be screened. Special attention was given to children in ordinary schools reported as showing any kind of deviant behaviour which might possibly be part of the syndrome, and to all children known to the local authority as handicapped in any way, physically or mentally.

The 135 children who were selected by the first screening process were then examined and given psychological tests, and further information on behaviour was obtained from a trained informant. As a result of this second screening process 61 children were retained in the series and a detailed social, medical, and developmental history was obtained from the parents, who were also tested on the Progressive Matrices and Mill Hill Vocabulary Scale.

Finally, all the available medical and social records were examined and the 54 children for whom sufficient information was available were divided into three groups according to a standard procedure. The "nuclear autistic group" all showed Kanner's two essential symptoms (but not necessarily the onset pattern) in marked degree—that is, lack of responsiveness to people and insistence on the preservation of sameness. The "non-nuclear autistic group" showed one or other of

---

* Medical Research Council Social Psychiatry Research Unit, Institute of Psychiatry, London S.E.5.

these symptoms but not both: all showed many other characteristics of the syndrome as well. The remaining "non-autistic group" showed only minor fragments of the syndrome.

The screening procedures used at each stage were assessed for reliability in various ways and found to be satisfactory. Several details of the mothers' accounts (motor milestones, birth weight, and presence or absence of certain behaviours) could also be checked, and were found to be reasonably reliable.

Results

Children

Table I shows the prevalence of affected boys and girls aged 8, 9, and 10 on the census day. If the nuclear and non-nuclear groups are combined the overall prevalence is 4.5 per 10,000 children of this age group, about twice that for blindness. There was an excess of boys in all groups, the highest male : female ratio occurring in the nuclear group (2.75 : 1). This is much higher than the highest ratio reported for subnormal children—for example, 1.7 : 1 (Malzberg, 1954).

TABLE I.—*Prevalence on 1 January 1964 Among Children Aged 8, 9, and 10 Residing in the County of Middlesex*

	Boys	Girls	Both sexes	Rate per 10,000
Nuclear autistic group	11	4	15	2·1
Non-nuclear autistic group ..	12	5	17	2·4
Total autistic children	23	9	32	4·5
Non-autistic group	13	9	22	—

Of the 15 children in the nuclear group five had an I.Q. above 55; the rest were untestable or below 55. Five of the 17 non-nuclear autistic children also had I.Q.s above 55. All these 10 children were boys.

Considering the nuclear and non-nuclear groups together, 22 children had a gradual onset from an early age, while 10 had a definite and recognizable setback in development, eight of the latter having a low I.Q. or being untestable at the time of the survey. Delay in motor or speech development (15 out of 32 had marked delay in sitting or walking) was also associated with functional level at the time of the survey.

Nine of the 32 autistic children were mute and a further 10 had only a very limited use of speech: all these were functioning at a low level of intelligence. Five of the eight children whose speech was less severely affected and all the five whose speech was almost normal had intelligence quotients above 55.

There was no evidence of any special likelihood for an autistic child to be first-born (17 out of 32, compared with an expected 15.3) or to have any other specific birth rank. Most autistic children had normal siblings. These was no deviation from the expected frequencies of maternal age at the time of birth of the autistic children. There was no excess of children weighing less than 5½ lb. (2,500 g.) at birth in the autistic children or their siblings, but one-quarter of the children in the non-autistic group were immature according to this criterion. Their siblings had a similar median birth weight but no excess of immaturity.

Significant complications during pregnancy and delivery were reported in 6 out of 28 autistic children for whom medical records were available, compared with 3 out of their 44 siblings (Fisher's exact probability=0.073). Nine (28%) of the 32 autistic children had recorded evidence suggesting neurological abnormality: four had convulsions (three of them beginning in the first year), three had abnormal E.E.G.s, one was deaf (due to rubella), and one had congenital protrusion of one eye and a history of severe coal-gas poisoning. Eleven of the 22 non-autistic children had an equivalent range of abnormalities.

Parents

The distribution of fathers' occupations is shown in Table II. (In the general Middlesex population there were 5.0% in class I, 18.5% in class II, 57.2% in class III, and 19.3% in classes IV and V.) The fathers of nuclear autistic children are particularly likely to have occupations in the upper two classes (9 out of 15).

TABLE II.—*Occupation of Fathers Classified by Social Class*

Social Class	Nuclear Autistic	Non-nuclear Autistic	Non-Autistic
I	5	2	0
II	4	3	5
III	4	9	12
IV, V	2	2	4
Total	15	16	21
Not known	—	1	1

The education of the parents differentiates the three groups of children even more clearly, as can be seen from Table III. The parents' scores on the Mill Hill Vocabulary Test confirm these results.

TABLE III.—*Actual and Percentage Distribution of Parents (Mothers and Fathers Combined) According to Educational Level Reached, For the Three Survey Groups*

Educational level	Nuclear Autistic		Non-nuclear Autistic		Non-Autistic	
	No. (1)	%	No. (2)	%	No. (3)	%
School up to 15 years only	7	25	19	59	34	81
School after 15, or technical or other formal training	12	43	9	28	7	17
Professional education or university graduate	9	32	4	13	1	2
Total	28	100	32	100	42	100

Data not known for two parents in each group.

The adoptive parents (father, graduate; mother, school after 15) were included for one child in the nuclear autistic group.

Significance (1) *v.* (2) *v.* (3): $\chi^2 = 24{\cdot}15$, d.f. 4, $P < 0{\cdot}001$.

Data on the mental health of parents were obtained for 28 of the 30 parents of nuclear autistic children (three admitted to psychiatric hospital), 32 of the 34 parents of non-nuclear autistic children (two admitted to hospital), and 42 of the 44 non-autistic children (one admitted to hospital). None of the parents of autistic children had suffered from schizophrenia, though affective disturbances were not uncommon. Information was also obtained about 283 siblings of 97 parents of children in the three groups, only one of whom was reported to have had an illness resembling schizophrenia (one of the mothers of a nuclear autistic child had a sister who had been admitted to an institution in the United States, and treated by leucotomy).

Thus of 189 parents, uncles, and aunts of the autistic probands, 6 (3.2%) had been admitted to hospital for psychiatric illness, a figure very little different from that for the general population. In addition, out of 86 siblings of autistic children three showed behaviour disorder and an I.Q. in the E.S.N. range, though none had a clear-cut autistic disorder.

Services

The Middlesex County Council (like the Greater London Council, of which it now forms part) was outstanding in its efforts to provide special facilities for handicapped children. It is inevitable, however, that facilities for autistic conditions, where education and medical procedures are still experimental, should lag behind those for children with other handicaps such as blindness or deafness.

In most cases the problem was picked up early enough, though eight children were not referred to specialists till after the age of five, when earlier referral might have been helpful. Roughly half the parents of autistic children were strongly critical of the advice they received about diagnosis, management, and placement when they saw a specialist (see Table IV).

TABLE IV.—*Mothers' Opinions on the Advice Received About Diagnosis, Management, and Placement of Their Autistic Children*

	Diagnosis		Management		Placement	
	No.	%	No.	%	No.	%
Satisfied	6	21	5	17	9	31
Dissatisfied but not strongly critical	9	31	11	38	4	14
Strongly critical	14	48	13	45	16	55
Total	29	100	29	100	29	100

Three mothers could not be interviewed.

These criticisms were not casual or unfair—many mothers made explicit allowance for the special diagnostic and placement difficulties posed by their children. Inadequate guidance about placement attracted most comment—patients felt they were not given sufficient information about the alternatives available and the possible consequences of any decision they might make. Many mothers felt that they should have been given a better account of what was the matter with the child, and nearly half said that they were offered little or no helpful advice about how to manage their children at home. One mother, for example, said that she was told at a paediatric clinic about her 3-year-old son: "He's mentally defective; there is no hope for him whatsoever," and that thereafter she was left on her own, "like a leper, a young mother with a young baby, clueless about what to do. The only advice I ever got was 'let him play in the garden with a ball.'" This might have been an extreme example, but many of the mothers gave accounts which indicated that the medical and social work specialists they saw had not always been able to devote sufficient time to skilled counselling (Lotter, 1966b).

Only 16 of the 32 autistic children were receiving education (half of them in Steiner schools). The rest had not been given a trial in a special education unit; in fact, most had received no schooling at all. The decision to place these children in a non-educational setting cannot therefore have been based on adequate information about their response to skilled teaching methods in classes specially designed to contain and manage their difficult behaviour.

Discussion

The true incidence of autistic conditions in early childhood would be higher than the prevalence estimated from the results of this survey if some children with mild autistic disorders improved to such an extent that they would not have been picked up at the age of 8, 9, or 10 by the methods used. In addition, there may well be an excess mortality in very severely affected children. On the basis of the present results there are about 1,400 children aged 5–14 with the nuclear syndrome in England and Wales and another 1,600 autistic children with a rather less clear-cut clinical picture. Of these 3,000, at least 1,000 have a testable intelligence quotient above 55, and many of the others would undoubtedly benefit from remedial education. These figures compare with 1,400 blind children, and 2,100 partially sighted children, receiving special education, in January 1962, in schools approved by the Department of Education.

The high male–female ratio, the greater likelihood of paranatal complications, the high proportion suffering from physical abnormalities, together with the symptoms of the condition (particularly the speech disorder), suggest an organic aetiology. It is interesting in this connexion that Ingram (1960) also found a high male–female ratio and a substantial proportion of upper-middle-class parents in his series of children with developmental aphasia. The speech difficulties of children with receptive aphasia are closely similar to those found in psychotic children (Rutter, 1966a).

There is clearly no genetic or familial relationship to schizophrenia; a finding which has been paralleled in every well-documented series. Adults resident for long periods in a mental hospital tend to develop the syndrome of institutionalism (Barton, 1959; Wing, 1962) and thus acquire an artificial clinical homogeneity. Autistic children are particularly vulnerable to an understimulating environment (Rutter, 1965), so that if they grow up in an institution they may come to look like other institutionalized patients. These behavioural analogies have no diagnostic implications, and in any case do not hold for children brought up in their own families and given adequate education. None of the positive features of schizophrenia, such as delusions or hallucinations or specific catatonic phenomena, occur in autistic children, nor do they develop in later life (Rutter, 1966b). Adult schizophrenics do not have a history of Kanner's syndrome in childhood nor a raised incidence of autistic conditions in their relatives. There seems to be no reason why the two classes of disorder should be confused.

The unusual distribution of parental occupations requires explanation, but no plausible hypothesis is immediately evident. It has usually been assumed that this distribution is due to educated parents seeking advice more efficiently and refusing to accept a diagnosis of mental subnormality. There is no evidence for this in our data. Since there were 14 autistic children whose fathers had occupations in classes I and II, there would have to be 46 in classes III, IV, and V in order to achieve the same distribution as in the general population, whereas only 17 were found. It is extremely unlikely, in view of the very thorough search of local health and education authority records, that as many as 29 children in classes III–V could have been missed.

Rimland (1964) argued that the child with infantile autism might be a homozygote for high intelligence but carry a high vulnerability to various noxia during pregnancy and delivery. In the past, explanations have been based on an assumption that educated women are less likely to give their children expert and loving care during the first few months of life. There is little sociological evidence for this view, and in any case most educated women do not have autistic children; indeed, most parents of autistic children also have normal children. Finally, there is no evidence from any of the numerous series of children who were *really* deprived of maternal love during early infancy—for example, those raised in unsuitable institutions from birth—that such conditions produce a high incidence of childhood autism. The aetiology of the condition therefore remains obscure, though one report suggests that tryptophan metabolism may be abnormal (Heeley and Roberts, 1965).

Services leave a great deal to be desired, though most of the problems experienced by parents in the survey were also mentioned by the parents of children of severely subnormal intelligence (Tizard and Grad, 1961). The special nature of the disorder, however, gives some of the difficulties extra weight. The child may appear alert and attractive in spite of his odd behaviour. When the specialists seem puzzled and offer little helpful advice, and adequate educational and other services are not available, the parents may become profoundly isolated. The recent special units that have been set up in the London area (for example, Elgar, 1966) should help to relieve this problem, as will the growing experience of paediatricians, psychiatrists, and social workers. The parents should, of course, always be put into touch with the appropriate voluntary organization (the National Society for Autistic Children).

Summary

A survey of children aged 8, 9, and 10 resident in the former County of Middlesex on 1 January 1964 showed that 4.5 per 10,000 had "autistic conditions of early childhood." This means that there are about twice as many autistic children in the country as there are blind children. There was a raised male–female ratio but no special birth order. Autistic children were more likely to have suffered from complications during pregnancy and delivery than their siblings, and one-half had marked delay in motor milestones. It was confirmed that the parents of autistic children (particularly those in the "nuclear group") were likely to be above average in educational attainment, occupational level, and intelligence. There was no evidence for a genetic or clinical relationship between early childhood autism and schizophrenia. Clinical and educational services still leave much to be desired.

Evolution of the Ventilatory Capacity in Chronic Bronchitis

PETER HOWARD,* M.A., B.M., M.R.C.P.

Brit. med. J., 1967, 3, 392–395

The forced expiratory volume (F.E.V.) and its derivative the indirect maximum breathing capacity (M.B.C.) are used as indices of airways obstruction in patients with chronic obstructive airways disease. Prevalence studies of particular populations or groups of normal subjects have shown the F.E.V. to decline linearly with age. It is agreed that the ventilatory capacity declines further with progression of obstructive airways disease, but little information is yet available about the rate and mode of decline, particularly in relation to the phase of illness. The results of a long-term follow-up study are now reported in which the changes in the F.E.V.$_{0.75}$ have been carefully observed in a group of patients with established chronic obstructive airways disease attending an outpatient clinic. Particular attention has been paid to the long-term changes in individual patients and also to the effects of acute exacerbations of symptoms. It was hoped that the information might lead to a better understanding of the progress of airways obstruction, which is generally believed to be the chief cause of disability in chronic bronchitis.

Methods of Study

A study was made of 112 men and 13 women attending the clinic on account of frequent exacerbations of chest illness or breathlessness, usually the latter. Patients were included who had been followed regularly for at least two years, and this was the major criterion for admission to the study. In 1962 the patients answered the Medical Research Council (1960) short questionary on respiratory symptoms. All except two patients admitted to a productive cough, but a further 10 thought it occurred less often than on "most days for three months of the year" (grade 0). Of these 10 patients, five had attacks of bronchial asthma defined as sudden attacks of reversible severe wheezing and breathlessness not associated with cardiovascular disease, one had hay-fever in the summer months, and four said they experienced frequent attacks of chest illnesses but denied the persistent production of sputum between attacks. Twenty-four patients said they produced sputum only in the mornings (grade 1) and 89 said that it was raised both in the mornings and throughout the day (grade 2). Therefore 123 patients could be classified as cases of chronic bronchitis of some severity (Medical Research Council, 1965). One hundred complained of breathlessness which limited them to their own pace on the level or of more severe disability, and only four denied any breathlessness. Of the 125 patients, 106 had suffered at least one attack of chest illness in the previous three years, but most of them experienced more frequent exacerbations than this. Three patients have developed congestive cardiac failure (cor pulmonale) during the period of observation.

The patients usually attend the clinic at monthly intervals or less in the winter-time and every two or three months in the summer. In the four years up to the end of 1965 the F.E.V.$_{0.75}$ and the forced vital capacity (F.V.C.) were measured by means of a Poulton spirometer (McKerrow, McDermott, and Gilson, 1960) on each visit by one of three trained technicians. The F.E.V. was read directly off this instrument as the indirect M.B.C. in litres per minute. Five serial recordings were taken, the result being recorded as the mean of the best three readings. Before 1962 the same measurements were made annually with a Collins–Gaensler spirometer. From this machine the absolute F.E.V.$_{0.75}$ was measured, corrected for temperature, and then multiplied by 40 to derive the indirect M.B.C. In a comparison of the two instruments no significant difference was found between consecutive readings on the same patients ($t=16.6$, $P<0.001$).

Since the initiation of these studies the indirect M.B.C. has become a less popular method of recording this type of measurement. Thus in the analysis of the data the figures have been divided by 40 to convert them to the F.E.V.$_{0.75}$ as they were originally measured. Though formulae are available for

---

* Department of Medicine, University of Sheffield, the Royal Hospital, Sheffield 1. Present address: Department of Environmental Medicine, Johns Hopkins University, 615 North Wolfe Street, Baltimore, Maryland 21205, U.S.A. Requests for reprints to Sheffield.

converting F.E.V.$_{0.75}$ to F.E.V.$_1$ this was not done in the present study, as such a conversion cannot easily be made without criticism (Pearson, Ashford, Brown, and Morgan, 1966). A regression of the change in F.E.V.$_{0.75}$ with time (in months) was calculated for each patient together with the standard deviation about the regression and the standard error of the slope. The connotation F.E.V. is used in this paper to represent F.E.V.$_{0.75}$. Ninety-seven patients have been followed for more than four years and their measurements were taken with both instruments. In 28 patients the Poulton spirometer alone was used.

At each attendance the patient was examined and treatment prescribed. Most patients were treated with aerosol sprays of isoprenaline and/or adrenaline and atropine and an oral bronchodilator drug such as theophylline monoethanolamine, choline theophyllinate, or orciprenaline. Courses of tetracycline (1 g. daily for seven days) or ampicillin (1 g. daily for seven days) were dispensed to treat individual acute exacerbations of symptoms as they occurred. In the past three years extra courses have been given as reserve supplies for the patient to take himself as soon as he felt that a further exacerbation was developing. A small number of patients also received prednisolone for associated bronchial asthma or chlorothiazide diuretics for congestive heart failure.

Results

The mean age of the patients was 60.7 (S.D.= ±9.86) years and Table I shows the age distribution. The mean period of follow-up was 7.1 years (range 2–13 years) and the mean initial F.E.V. 1.2 (S.D.= ±0.165) litres. Fig. 1 shows the distribution of the initial F.E.V. The regression coefficients were expressed in litres per year, and only four out of the 125 patients had a positive regression coefficient. The mean regression coefficient for the whole group was −0.0834 (S.D.= ± 0.0667) litre per year. Fig. 2 shows the distribution. The mean standard deviation about this slope was ±0.162 litre and the mean standard error of the slope ±0.0221 litre per year. The death rate has been followed since 1962, and up to the end of 1965 13 patients had died. Their mean age at death was 64.7 years and their mean regression coefficient −0.0930 litre per year, values which were slightly larger than those of the group as a whole.

TABLE I.—*Age Distribution of the* 125 *Patients*

Age in 1965	<39	40–49	50–59	60–69	70–79
No. of patients ..	5	7	33	62	18

The regression coefficients were plotted against age in 1965, the mean F.E.V. (calculated from the sum of all measurements divided by the number of measurements on each individual), and the years of follow-up. A statistically significant regression was obtained with age in 1965 (t=2.57, P<0.02) and with the mean F.E.V. (t=4.95, P<0.001). The regression equations were:

$$y = -0.00154 \text{ age} + 0.0101$$

$$y = -0.0648 \text{ mean F.E.V.} - 0.0308$$

The regression coefficients were plotted on the ordinate. Thus the rate of fall of ventilatory capacity showed a small decline with age in this particular group of hospital patients. The rate of fall was also related to the mean F.E.V. The mean point was used rather than the initial F.E.V. as the use of the latter is apt to give spurious correlations (Oldham, 1962). The mean F.E.V. was not related to age (t=0.6, P>0.6) and was therefore an unlikely explanation of the age effect. Fig. 3 shows the plot of regression coefficient against years of follow-up, for which a regression was not calculated on account of the changing

The dots on the abscissa represent 1 January of each year and the short vertical lines the time of occurrence of an exacerbation for which a course of antibiotics was given.

variance. The variance would be expected to be higher in those followed for only a short period, simply on account of the smaller number of observations possible, but also because of the tendency for those with higher rates of decline of ventilatory capacity to die or leave the clinic after being followed for only short periods. This may also be a factor in the explanation of the reduced rate of fall of ventilatory capacity with increasing age.

Inspection of the individual curves, particularly from the past four years when more measurements were available, revealed several points of interest. Seven patients (Fig. 4A) showed wide fluctuations of the F.E.V. All of these patients had bronchial asthma, and despite the large swings of F.E.V. many had large regression coefficients. In the remainder, forming the majority of patients and excluding those who improved, the F.E.V. declined at various rates with a variable fluctuation about the regression. Fig. 4B illustrates this picture. The "fluctuation" in 25 patients showed a seasonal variation, with troughs of low F.E.V. appearing in the winter months and the peak values in the summer (Fig. 4C). In half of the total number of patients no specific pattern to the variations could be discerned (Fig. 4D), but their amplitude remained relatively constant in any individual.

Disregarding the seasonal and spontaneous fluctuations, the rate of decline of F.E.V. in any one patient tended to remain constant for long periods, in some throughout the whole of the period of their observation. For example, in 19 out of 28 patients who had been followed for more than 10 years a straight line could easily be drawn by eye through the values obtained throughout the whole period. However, in a number of cases, excluding the "asthmatic" curves, there occurred sharp falls of F.E.V., arbitrarily defined as a loss of F.E.V. within six months or less, greater than two standard deviations from the regression. Twenty-one such incidents have occurred in 19 patients during the past four years. Fig. 5 gives two examples. Seven recovered completely within a year, usually within three months, three recovered between one and two years (Fig. 5A), four made a partial recovery, and in seven there was no recovery at all. The curves of the last-mentioned group thus showed a downward step, and the path of the regression usually intersected the step some way about its mid-point. The ruling of a departure by two standard deviations from the regression had to be relaxed on this account in some of these cases, but in all a step in the function curve was clearly visible. Fig. 5B was such a case. The pattern of the F.E.V. curve has continued after the sharp fall in the same manner as before. The patients showing the sharp falls of ventilatory capacity did not differ clinically, as judged by the replies to the M.R.C. questionary, from those who did not show these changes.

The cause of the 21 sharp falls of function was investigated, and Table II shows the various illnesses which could be associated with them in time. In only 10 patients could an acute exacerbation, however mild, be implicated, and in six no change in clinical status had apparently occurred. Some even maintained that they were as well as they had ever been. Though the sharp falls of function appeared slightly more often in the winter months (Table III), there was no significant seasonal factor. Smoking habits were not recorded in detail at the time of occurrence, but appeared to be a factor in that replies from the questionaries completed in 1962 (Table IV), indicated that those patients showing the sharp functional alterations were more persistent smokers than those who did not have these changes.

Remaining patients	106	34 (33)	11 (10)	43 (41)	8 (7)	10 (9)
Total	125	45 (36)	15 (12)	46 (37)	8 (6)	11 (9)

The relation between acute exacerbations of symptoms and the rate of fall of the F.E.V. was examined further. In each patient the time of occurrence during the past four years of acute exacerbations for which antibiotics were given was marked on the F.E.V. curve. The majority showed no more than a minor fall of the F.E.V. The regression coefficients were plotted against the number of courses of antibiotics prescribed per year in the past four years for all patients, and the relation was just significant at the 5% level of probability ($t=2.04$, $P<0.05$).

Finally, the change in F.E.V. was compared with the change in F.V.C. in those patients showing the sharp falls of function. F.E.V./F.V.C. and F.V.C. were plotted against time, and in 16 patients out of the 19 both fell, indicating that the decline in F.E.V. could be partly accounted for by a fall in vital capacity. In a number of the remaining patients picked at random the same trend was evident throughout the period of follow-up.

Discussion

The patients in this study are a highly selective sample of those with chronic obstructive airways disease. Most of them were referred to the clinic only when they became breathless, when they became unable to work, or when their symptoms were difficult to control. Many of these patients had the most severe forms of the disease. A minimal period of follow-up of two years, preferably three, was arbitrarily fixed in order to accumulate enough observations to plot a reasonable regression. This policy discriminated against a few patients with steep regressions who presented to the clinic with a low F.E.V. (<1). The death rate was underestimated, as it was not recorded before 1962 and patients followed up from that period would constitute a survivor population. Both of these factors, however, would tend to lead to an underestimation of the mean regression coefficient. Despite these difficulties, several important features are shown. Firstly, the average rate of fall of ventilatory capacity is very much higher than other figures reported so far; secondly, the rate of decline is very variable even in patients with established disease, some patients having particularly steep rates of fall; and, thirdly, though most patients appear to lose function in a reasonably linear manner, a number exhibit sharp drops which do not recover. These points are discussed below in more detail.

The progressive deterioration of function occurred in all but four patients. It could not be accounted for by the ageing of the population, and it continued despite careful symptomatic treatment administered in the clinic. The mean regression coefficient of -0.0834 litre per year is larger than other reported figures. Higgins and Oldham (1962), in a five-year follow-up of miners and non-miners in the Rhondda Fach, found an overall loss of 0.0472 litre per year. Age correlations from prevalence studies have been used to calculate the rate of deterioration of ventilatory capacity. Baldwin, Cournand, and

Richards (1948) thus found a fall of 0.013 litre per year (calculated from the direct M.B.C.), Kory, Callahan, Boren, and Syner (1961) a fall of 0.025 litre per year (calculated from F.E.V.$_{1}$), and Ferris, Anderson, and Zickmantel (1965) a fall of 0.024 litre per year (also calculated from F.E.V.$_{1}$), all in healthy males after standardizing for body size. Preliminary figures from a companion study of a slightly younger male group of 142 workers from a Sheffield steel and chemical plant followed since 1956, using the same spirometers, reveal a mean regression coefficient of the order of -0.03 litre per year up to the end of 1965. The expression of the decline in ventilatory capacity as a regression coefficient is a useful index of the overall decline and one measure of the severity of the disease.

Though a detailed follow-up of the ventilatory tests has been in progress for only four years, it would appear that the path of the mean F.E.V. does fall in a reasonably linear manner in many patients for periods of at least several years. The slope is very variable, but sufficient clinical and physiological information is not yet available to compare and contrast patients with differing rates of deterioration of ventilatory capacity. The sharp alterations of ventilatory capacity seen in some patients were surprisingly infrequent, as it was expected that the exacerbations of the disease would have had a much greater effect on the F.E.V. curve. It is true that in outpatient clinics attendances may have been missed at the peak of illness and some sharp falls therefore gone unnoted. However, many exacerbations were observed in the acute phase and most at some stage during recovery, and still significant decreases of F.E.V. were relatively infrequently found, and closer study is warranted.

The significance of the sharp falls of function that were observed cannot yet be fully evaluated. In particular, information is needed to determine how often they occur during the natural history of the disease, and whether they develop in persons with completely normal function. The findings suggest that chronic bronchitis is associated with some pathological process which is responsible for a steady erosion of ventilatory capacity, but that the same or a different process exacerbates the decline at certain times. Since a complete recovery of function was observed in only half of the instances where steep falls occurred, the latter must contribute to at least part of the overall decline.

Several factors are thought to play a part in the cause of chronic bronchitis, such as smoking, atmospheric pollution, and bronchial infection. Tobacco consumption has not been studied in detail, but it was clear from the replies given to the questionary in 1962 that those who subsequently showed the steep falls of ventilatory capacity were more persistent smokers than those who exhibited a steady deterioration. It is hoped, at a later date, to prepare a more detailed analysis of the relation between smoking habits and the decline of ventilatory capacity.

The significance of bronchial infection is difficult to assess. The acute exacerbations so characteristic of the disease have been attributed to bronchial infection on clinical grounds and by the isolation of pathogenic organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae* from the sputum. Pathologists looking at the terminal phases of the disease have suggested that bronchial infection plays an important part in the development of destructive lung changes (Leopold and Gough, 1957; Reid, 1961). In controlled trials of the prophylactic use of antibiotics the total period of disability from exacerbations has been found to be reduced but the number of exacerbations unaffected (Murdoch, Leckie, Downie, Swain, and Gould, 1959; Francis and Spicer, 1960; Francis, May and Spicer, 1964). This suggests that the acute exacerbations are initiated by factors unrelated to bacterial infection but may be prolonged by its secondary effects.

Whatever the causes of the acute exacerbation, this study shows that the majority had very little effect on the individual F.E.V. curves but there was some correlation between the rate of deterioration of function and the number of courses of antibiotic prescribed. Though the establishment of a correlation does not prove a causal relation, it is possible that bronchial infection is a factor in the steady erosion of ventilatory capacity. But in a controlled trial of chemotherapy undertaken by the Medical Research Council (Fletcher, 1965; Medical Research Council, 1966) no difference was found in the deterioration of function between patients showing a large number of respiratory illnesses and frequent periods of mucopurulent sputum and those without these features. In a quarter of the patients in the present study who exhibited sharp falls of ventilatory capacity clinical evidence of a coincident exacerbation could not be obtained. Thus, although bacterial infection recognizable on clinical grounds and frequent exacerbations of disease may contribute, they do not seem to be essential to the decline of ventilatory capacity.

Summary

A follow-up study of the F.E.V.$_{0.75}$ in 125 patients with chronic obstructive airways disease attending an outpatient clinic is presented. The mean age of the group in 1965 was 60.7 years and the mean period of follow-up 7.1 years. The mean rate of fall of F.E.V. expressed as a regression coefficient was 0.0834 litre per year and considerably greater than that so far reported in normal subjects or other populations.

In the past four years a detailed study has been made of all patients whose F.E.V. was measured on every attendance at the clinic. Several varieties of F.E.V. curves are described. The size of individual regression coefficients was very variable even in patients with severe disease. There was some relation between the size of the regression coefficient and the number of acute exacerbations of the disease requiring antibiotic therapy, but, in individual plots, acute chest illnesses in the majority had no more than a minor effect on the F.E.V. curve. Yet on 21 occasions in 19 patients in the past four years steep falls of the F.E.V. (a loss greater than two standard deviations from the regression occurring within six months or less) were observed. One-quarter of these episodes could not be associated with any chest illness, however mild, and in only half was a good recovery of function observed. These results are discussed in regard to the aetiology of obstructive airways disease.

I am grateful to Professor C. H. Stuart-Harris for his encouragement and constructive criticism of this work. I also thank Miss Victoria Home, who made most of the measurements of forced expiratory volume. This work was supported in part by grant No. H.E. 04775 from the National Heart Institute, U.S. Public Health Service, and in part by the Board of Governors of the United Sheffield Hospitals.

Management of Incoordinate Uterine Action under Continuous Epidural Analgesia

DONALD D. MOIR,* M.B., CH.B., F.F.A. R.C.S., D.A., D.OBST.R.C.O.G. ; JAMES WILLOCKS,* M.D., M.R.C.O.G.

Brit. med. J., 1967, 3, 396–400

British anaesthetists and obstetricians have made little use of epidural analgesia in obstetrics. From time to time small series have been reported by British workers who have used caudal or lumbar epidural analgesia in incoordinate uterine action (Galley, 1949 ; Johnson, 1952, 1954, 1957 ; Arthur and Johnson, 1952 ; Ball and Chambers, 1956 ; Tunstall, 1960) and in pre-eclampsia and eclampsia (Bryce-Smith and Williams, 1955 ; Scott, 1955).

In contrast, epidural techniques are extensively used for obstetric analgesia in many North American centres (Bush, 1959 ; Hingson *et al.*, 1961 ; Hellmann, 1965 ; Moore, 1966) following on the pioneer work of Hingson and Edwards (1943). The reasons for this difference in practice are several.

Firstly, British obstetric opinion is generally in favour of encouraging spontaneous delivery where this can safely be achieved, and most spontaneous deliveries are conducted by midwives in hospital and at home. Epidural analgesia, because it produces perineal anaesthesia and so abolishes the reflex expulsive efforts of the second stage of labour, is usually associated with a high forceps delivery rate.

Secondly, epidural analgesia may be required at any time of the day or night, and its safe conduct necessitates the presence of an anaesthetist experienced in the technique for as long as the block is maintained. This demands a 24-hour obstetric anaesthetic service by experienced anaesthetists who are not committed to other duties. This service exists in few hospitals in Great Britain today, though in our experience the benefits are substantial and not confined to the administration of epidural analgesia.

Finally, there exist anaesthetists and obstetricians who believe, despite impressive evidence to the contrary, that epidural analgesia is a difficult and dangerous technique. With experience the success rate can approach 100%, particularly in younger women without spinal deformities or the ossification of the supraspinous ligament which may develop in the elderly. The potential dangers of epidural analgesia should not be minimized, but with awareness of these dangers and constant attention to details in technique and management by a team of anaesthetists, obstetricians, and midwives the method is acceptably safe. The vast experience of others confirms this safety. Norris *et al.* (1960) reported over 9,000 epidural blocks in labour, and Hellmann (1965) reported over 26,000 cases. In neither series was there any foetal or maternal mortality attributable to epidural analgesia, and the incidence of complications was very low. Continuous observation is essential for safety, and an extra burden is thereby placed on nursing staff, who, in our experience, accept this willingly when convinced of the value of the procedure.

It is not our intention, however, to advocate the routine adoption of epidural analgesia for relief of pain in normal labour. In the Queen Mother's Hospital, Glasgow, continuous lumbar epidural analgesia is used in just over 4% of all labours and, in addition, "single-shot" epidural analgesia is used for 9% of mid-cavity forceps deliveries. During the last two and a half years 246 continuous epidural blocks have been given to patients in labour. In the 100 cases reported here the indication was incoordinate uterine action. The present review was undertaken to assess the contribution made by epidural analgesia to the management of these cases.

Anaesthetic Technique

The lumbar rather than the caudal approach to the epidural space is preferred because of the higher success rate, the lower dose of local anaesthetic drug, and because the skin of the lumbar region seems less open to contamination than the skin over the sacral hiatus. The caudal approach is used when abnormalities of the lumbar spine are present.

Lumbar epidural puncture is performed with the patient in the sitting position to encourage spinal flexion, which may be difficult to achieve in the lateral position because of the gravid uterus. A 16 S.W.G. Tuohy needle is used and the epidural space is identified by the loss-of-resistance technique. A plastic catheter (Lee, 1962) with a blunt tip (Moir and Hesson, 1965) is then advanced into the epidural space, the needle is withdrawn, and the catheter is connected to a sterile plastic 50-ml. syringe filled with local anaesthetic solution. This syringe is now sealed inside a transparent bag (Cole, 1964) and strapped to the abdominal wall. This system allows top-up injections to be given without scrubbing-up and seems to avoid the risk of accidental overdosage associated with at least one of the drip techniques (Edmonds-Seal, 1964). Free mobility is permitted as there is no infusion apparatus connected to the patient.

The drug used is 2% lignocaine with 1:200,000 adrenaline added. Doses are varied slightly with maternal height and range from 6 to 9 ml. (120 to 180 mg.) of lignocaine. A larger dose of 10 to 12 ml. (200 to 240 mg.) is given before operative vaginal delivery to ensure perineal analgesia and relaxation of the pelvic floor muscles. The use of 2% lignocaine permits more injections to be made from the 50-ml. syringe than would be possible if weaker solutions were used. The percentage strength of lignocaine solution injected does not greatly influence the extent of analgesia obtained (Bromage, 1962).

Doses of lignocaine are kept as low as possible to minimize the risk of hypotension and because the free spread of solutions in the epidural space of the pregnant woman is recognized and probably attributable to engorgement of the epidural veins (Bromage, 1962). Prilocaine (Citanest) is not used, because repeated injections would be expected to produce considerable methaemoglobinaemia (Adamson and Spoerel, 1966).

Complications

The following complications were observed in the 100 cases reported here.

Dural Puncture.—This occurred in two patients. In one case the epidural catheter probably punctured the dura (Moir and Hesson, 1965) and spinal anaesthesia resulted. In the other case no injection was made. In neither case did mother or infant suffer harm.

Puncture of an Epidural Vein.—This was observed three times after passage of the catheter. No injection was made

---

* Queen Mother's Hospital, Glasgow C.3.

until the catheter had been displaced from the vein (in one case by repuncture at another interspace) and there were no harmful consequences.

Paravertebral Passage of the Catheter.—This occurred once. Only a narrow unilateral area of cutaneous anaesthesia developed and it was presumed that the catheter had passed out through an intervertebral foramen. Repeat puncture was satisfactory.

Toxic Effects of Lignocaine.—None was observed. The dose of lignocaine, with adrenaline, was always less than 250 mg. at each injection.

Hypotension.—Transient falls in systolic blood pressure to below 90 mm. Hg were seen on 15 occasions in 100 epidural blocks in which almost 600 injections were given. This represents an incidence of about 2.5 per 100 injections. In 13 instances the hypotension responded immediately to turning the patient into the left lateral position and was attributed to the supine hypotensive syndrome. In the other two cases an intravenous injection of methoxamine 3 mg. restored normal blood pressure. This drug is better avoided because it can cause foetal bradycardia and tetanic uterine contraction (Vasicka *et al.*, 1964) and constriction of uterine arteries (Greiss and Wilkes, 1964), and vasopressor drugs have not been used in our hospital during the last year.

Other Complications.—Retention of urine may, of course, complicate any labour, but is more likely to occur when bladder sensation is lost under epidural analgesia.

Lumbar-puncture headaches do not occur after epidural analgesia. No foetal or maternal mortality is attributable to the anaesthetic technique.

Tachyphylaxis

This has been discussed elsewhere (Moir and Willocks, 1966). We use this term to mean a substantial reduction in the duration of analgesia obtained after repeated injections of local anaesthetic drug. The phenomenon was seen in over 60% of cases where four or more top-up injections were required, and in 70% of these cases analgesia eventually lasted less than half as long as it had after the initial injection. This rather troublesome phenomenon is unexplained and has seldom been noted by others, though Bush (1959), Bromage *et al.* (1964), and Cox and Spoerel (1964) refer to it. Perhaps tachyphylaxis has been infrequently observed because epidural analgesia is not commonly given for the prolonged periods used in these incoordinate labours (average duration 10½ hours) where pain may be increasing rather than decreasing during the block.

Description of Cases

Continuous epidural analgesia was administered to 100 women with incoordinate labour in the Queen Mother's Hospital from March 1964 to July 1966—1.4% of the deliveries in that time.

In this highly selected group of abnormal cases conventional treatment had failed and the decision had to be taken whether to perform caesarean section without further prolongation of labour. Maternal distress and failure to respond to analgesic drugs, combined with incoordinate uterine action, were the criteria for the use of epidural analgesia. Incoordinate uterine action was a clinical diagnosis—contractions of varying frequency and strength which failed to dilate the cervix and bring the presenting part down in the normal way; most cases were of the hypertonic type associated with distressing pain and backache, but often hypertonic and hypotonic periods occurred in the same labour, as observed by Jeffcoate (1961). When periods of hypotonic uterine action were prominent an oxytocin drip was used: 29 patients had an oxytocin drip at some point after the institution of continuous epidural analgesia. As there was no consistent policy on the use of oxytocin, further comment on this aspect of treatment is difficult. Our impression is that in some cases a more liberal use of oxytocin would have been beneficial.

In a few cases the abnormal pattern of uterine contractions was confirmed by tocodynamometry.

On reviewing the cases thus selected we found that they exhibited many of the general features classically associated with incoordinate labour, such as short stature, postmaturity, large size of foetus, and occipitoposterior position (Table I). Ninety-two of our patients were primigravidae; the remaining eight were in their second pregnancy and all of them had a history of prolonged labour, five having previously been delivered by caesarean section early in labour. Eighty-eight patients were under the age of 30 and none was over 35. Fifty-three patients had labour induced by rupture of the membranes, pre-eclampsia and postmaturity being the most common indications. The average duration of labour before the block was given was 23 hours. Vomiting, pyrexia, tachycardia, and ketonuria were common and intravenous glucose was freely used (Table II). When the membranes had been ruptured for more than 24 hours an antibiotic was given—usually ampicillin 500 mg. every six hours by intramuscular injection.

TABLE I.—*Features Associated with Incoordinate Labour in This Series*

Primigravidae	92%
Age <30 years	88%
Height <61 in. (155 cm.)	40%
Gestation >41 weeks (287 days)	50%
Foetal weight >8 lb. (3·63 kg.)	49%
Occipitoposterior position	65%
Surgical induction of labour (amniotomy)	53%

TABLE II.—*Physical Findings in* 100 *Patients with Incoordinate Uterine Action*

Tachycardia (over 100/minute)	66%
Pyrexia (over 37·5° C.)	38%
Ketonuria	78%
Vomiting	34%
Intravenous drip given	86%

The average duration of labour after epidural block was 10.2 hours and the average total duration of labour 33,25 hours.

Effect of Epidural Block on Progress of Labour

Epidural block was given only after the cervix was 4 cm. dilated; once begun, analgesia was maintained continuously until delivery. Progress in labour was estimated by recording the frequency, duration, and intensity of uterine contractions by abdominal palpation and by assessing cervical dilatation by rectal and vaginal examination.

To obtain an objective assessment of the rate of progress in labour before and after epidural block we prepared, in retrospect, a graph or "partogram" (Rodesch *et al.*, 1965) for each of our cases, employing the method of Friedman (1955), who has made extensive studies of the graphic analysis of labour (Friedman, 1954, 1956; Friedman and Sachtleben, 1961a, 1961b, 1962a, 1962b, 1963a, 1963b, 1965). Friedman assesses progress of labour by graphing cervical dilatation against time because "the dilatation of the cervix is the result of all the driving force of uterine contractions acting upon the uterine contents and against the resistance of the maternal soft parts," and thus is the best index of progress in labour (Friedman, 1965). In the normal primigravida, Friedman (1955) has shown that cervical dilatation in the "active phase" of the first stage of labour (after 3 cm.) progresses in an almost linear fashion.

In our cases we compared (*a*) the rate of cervical dilatation in the time from 3 cm. (when the "active phase" usually begins) until the epidural block was given with (*b*) the rate from epidural block until delivery. We avoided any comparison which included the "latent phase" before 3 cm. dilatation, as this would have given a false impression of an increased rate of dilatation after epidural block. In all cases the records of vaginal rather than rectal examinations were used to construct the graphs.

In three cases there was insufficient information to make a calculation, but the results for 97 cases were that the rate of dilatation after epidural block was increased by at least one and a half times in 68 cases (70%). Dilatation proceeded at an unchanged rate in 18 cases (18.6%) and was slowed in 11 cases (11.3%) (see Table III).

TABLE III.—*Rate of Cervical Dilatation After Epidural Block in 97 Cases of Incoordinate Uterine Action*

Rate	No. of Patients	Percentage
Increased by more than 3 times ..	44	45·4
Increased by 1½ to 3 times	24	24·7
Unaltered	18	18·6
Slowed	11	11·3

As has already been pointed out, only a minority of patients had oxytocin drips, usually for short periods, and there was no consistent policy on the use of oxytocin. The response of the uterus to epidural block did not seem to be related to the use of oxytocin.

The method of delivery is shown in Table IV. Caesarean section was performed in 26 cases: five of these had already reached the second stage of labour and an attempt at vaginal delivery had failed because of mechanical difficulty, while in another two cases an attempt at vaginal delivery was thought inadvisable though the cervix was almost fully dilated. The findings regarding progress in labour and eventual method of delivery should be interpreted in the light of the presence or absence of cephalopelvic disproportion.

TABLE IV.—*Method of Delivery in 100 Cases of Incoordinate Uterine Action Treated by Epidural Block*

Caesarean section	26	Vacuum extraction	21
Forceps	48	Spontaneous	5

Effect of Cephalopelvic Disproportion on Results

Glasgow was at one time notorious for its high incidence of contracted pelvis, and dystocia from this cause is still commoner than in most areas in the United Kingdom, though severe and obvious pelvic contraction such as that caused by rickets is now seldom seen and the diagnosis of cephalopelvic disproportion is often made only in labour or at delivery. Antenatal examination had already excluded major degrees of contracted pelvis in the patients of this series, but in 29 cases it was found that disproportion, usually associated with malposition of the foetal head (particularly occipitoposterior), caused appreciable mechanical difficulty in labour or at delivery.

Jeffcoate (1965) reiterated that small women with large babies are liable to have incoordinate labours. Forty of our patients were 61 in. (155 cm.) or less in height: disproportion was present in 16 (40%) of these and 10 of the 16 babies weighed 8 lb. (3.63 kg.) or more, while in the remaining 24 short women (60% of the group) disproportion was not present though 10 of the babies weighed more than 8 lb. (3.63 kg.).

There were 60 patients whose height was more than 61 in. (155 cm.). Disproportion was present in 13 (22%) of these, and 8 of the 13 babies weighed more than 8 lb. (3.63 kg.), while in the remaining 47 (78.3% of the taller group) there was no disproportion and 21 of the 47 babies weighed more than 8 lb. (3.63 kg.).

The rate of cervical dilatation before and after epidural block in cases with and without cephalopelvic disproportion is shown in Table V, from which it appears that disproportion did not significantly alter the improvement in uterine action in response to epidural block.

In contrast Table VI shows that disproportion was the most important factor influencing the method of delivery, the caesarean section rate being 55.2% in cases with, and 14.1% in cases without disproportion.

TABLE V.—*Rate of Cervical Dilatation After Epidural Block in Cases With and Without Disproportion*

Rate	70 Cases Without Disproportion	27 Cases With Disproportion
Increased by more than 3 times ..	34 (48·6%)	10 (37·0%)
Increased by 1½ to 3 times ..	18 (25·7%)	6 (22·2%)
Unaltered	12 (17·1%)	6 (22·2%)
Slowed	6 (8·6%)	5 (18·6%)

TABLE VI.—*Method of Delivery in 100 Cases of Incoordinate Uterine Action Divided According to Presence of Disproportion*

	29 Cases With Disproportion	71 Cases Without Disproportion
Caesarean section	16 (55·2%)	10 (14·1%)
Forceps	11 (37·9%)	37 (52·1%)
Vacuum extraction	2 (6·9%)	19 (26·8%)
Spontaneous	0	5 (7·0%)

When an increased rate of dilatation followed epidural block in cases with disproportion the caesarean section rate was 27.6%, whereas if the rate of dilatation was increased and no disproportion was present the caesarean section rate was only 3.8%.

Blood Loss at Delivery under Epidural Block

The average blood loss, recorded accurately by a haemoglobin-dilution technique, at forceps delivery in 33 of our cases was 371 ml. Only 2 (6%) of these patients lost more than 500 ml. These figures compare favourably with blood loss at forceps deliveries under general anaesthesia (where the average loss was 412 ml. and the incidence of postpartum haemorrhage was 29%) (Moir and Wallace, 1967).

It is our impression that the principal source of bleeding at delivery under epidural block is the episiotomy rather than the placental site and that uterine retraction is excellent. There is no evidence that the management of incoordinate labour under epidural analgesia predisposes to postpartum haemorrhage.

Foetal Mortality and Morbidity

There was one stillbirth and one neonatal death in the series, giving a perinatal mortality of 2%. An account of these deaths is given in the discussion.

The Apgar score of the 99 liveborn babies was estimated two minutes after birth. Sixty-six babies (66.6%) had a score of 7 or over. Seventeen babies (17.1%) had a score of 4 or less. The number requiring active resuscitation (by intubation or hyperbaric oxygenation) was 15. There were three cases of intrauterine pneumonia or meconium aspiration syndrome and three cases of transient cerebral irritation. No other serious complications occurred and all 98 surviving babies were dismissed apparently well.

Maternal Morbidity

The stay of the mothers in hospital after delivery was of normal duration.

Puerperal pyrexia of 37.6° C. (99.7° F.) or over occurred transiently in 24 patients. One patient was readmitted two weeks after delivery with a genital infection.

Discussion

One hundred women were given continuous epidural analgesia because they were having painful incoordinate labours. Review of these cases showed a high incidence of young primigravidae, short maternal stature, large foetal size, and occipitoposterior position (Table I).

Twenty-nine patients had appreciable mechanical difficulty in labour or at delivery because of minor degrees of disproportion, often in association with occipitoposterior position. Mechanical difficulty of this kind has proved to be the most important factor influencing the method of delivery, and if such cases could be excluded treatment would be much simplified and the results would be better. Experience with this series, however, has confirmed our belief that it is seldom possible to predict mechanical difficulty in labour by antenatal examination except in gross cases of disproportion. The position and attitude of the foetal head are important, but in the borderline case it is the action of the uterus which is the most important factor, and in the primigravida this is completely unknown until labour begins. Often it is only after labour is far advanced that the mechanical problem becomes evident; if pain is abolished by epidural block there is usually nothing to lose by waiting until the diagnosis is clear.

With relief of pain, the patient's general condition may be improved out of recognition, but the obstetrician should always remember the dangers of disproportion and should not strive too zealously for a vaginal delivery. Even "trial of forceps" with the theatre set for caesarean section is not always a safeguard, as the following case illustrates.

A primigravida aged 27 had an incoordinate first stage of labour lasting 45½ hours, the last 20 hours being managed under epidural analgesia. After an hour in the second stage a trial of vaginal delivery was attempted. The vacuum extractor was applied without success and rotation and traction with Kielland's forceps produced no advance. For the first time disproportion was now detected. Caesarean section was performed and the child (weight 3.9 kg.) died five hours later of intracranial haemorrhage from tentorial tears.

When the fault in labour is principally one of uterine action epidural analgesia helps considerably in allowing labour to continue painlessly and with a likelihood of improving uterine action until the second stage is reached, and there is a low caesarean section rate in such cases. It is difficult to assess whether epidural block has a stimulating effect on the progress of labour, even though a graphic analysis showed an increased rate of dilatation in 70% of cases, for some patients also had oxytocin drips and all had dehydration and acidosis corrected as required. Both clinical experience and in-vitro evidence (Mark, 1961) suggest that acidosis impairs uterine action.

Two infants have been lost. One, already described, died from intracranial haemorrhage. The details of the other case are as follows:

A primigravida aged 23 had labour induced at 41½ weeks. She had a hypertonic incoordinate labour (with marked dehydration, acidosis, and bowel distension) for 28 hours, when epidural analgesia was induced. Two hours later the foetal heart was not heard. At no time was maternal hypotension detected and there was no warning irregularity of the foetal heart or meconium staining. A stillborn child was delivered 19 hours later with considerable difficulty, the vacuum extractor being used as the cervix was not yet fully dilated. This case illustrates the need for greater information about the condition of the child in utero, particularly when labour is prolonged. Few other patients in our series have had perhaps an equally unsuitable environment for the baby.

The perinatal mortality rate for the hospital is 3.8%. The present series is small and a foetal loss of 2% is probably acceptable for those difficult cases, but it must be remembered that few premature babies were included. Comparable figures for foetal loss are 2.5% for labours lasting more than 24 hours (Royal Maternity Hospital, Belfast, 1963), 4.1% for labours longer than 30 hours (National Maternity Hospital, Dublin, 1964), and 7.6% for labours longer than 48 hours (Glasgow Royal Maternity Hospital, 1962). Separate figures for incoordinate labour are difficult to obtain, as this does not usually appear as an entity in hospital reports.

The acceptable condition of most infants in the series is shown by the Apgar scores and the low incidence of serious complications already quoted.

It is unnecessary to give depressant analgesic drugs to patients under epidural block, and this means that the child is more easily stimulated to take his first breath.

The value of antibiotic treatment in preventing the child becoming infected in utero is not precisely known, but further studies will probably soon elucidate this. Ampicillin, which is probably the most effective drug for the purpose (Williams and Felton, 1966; Blecher *et al.*, 1966), was used when the membranes had been ruptured more than 24 hours or when there was pyrexia.

The obstetric policy in this series has been conservative, as is indicated by a caesarean section rate of 26%, but there is no doubt that good results have been obtained in many places by a much wider use of caesarean section. The radical attitude adopted now in some centres is illustrated by the figures from the Royal Maternity Hospital, Belfast (1963), where the caesarean section rate for cases of abnormal uterine action without disproportion was 80%, there being no foetal loss, and the caesarean section rate for cases of contracted pelvis was 91.8%, the foetal loss being 2%.

It is our opinion that such a high caesarean section rate is not justified for incoordinate labour in the young primigravida because the uterine dysfunction is unlikely to recur in a subsequent labour if the cervix reaches at least half dilatation in the first labour (Jeffcoate *et al.*, 1952; Jeffcoate, 1961). In the older patient earlier resort to caesarean section is, of course, justified. The woman who has once been delivered by caesarean section faces a risk at subsequent confinements, whether or not a policy of repeat section is followed. Caesarean section is not always the easy and atraumatic operation that it ideally should be, and the postoperative complications are not negligible, the risk of thromboembolism, for example, being nearly six times greater than after vaginal delivery (Claye, 1961).

Incoordinate labour is often terminated by caesarean section because of maternal distress. Our object in using epidural analgesia has been to abolish pain so that time is available for the problem to be resolved to the extent that the woman either has a safe vaginal delivery or is delivered by caesarean section after the cervix is at least half dilated. When the patient has been completely relieved from pain the obstetrician can review the case more calmly; he may then reflect on the maxim of William Smellie (1752) that "it takes more skill to prevent than to perform an operation."

There is no doubt that the method demands both time and skill from a team of obstetricians, anaesthetists, and midwives.

Of the value of epidural analgesia in the management of incoordinate labour we are entirely convinced. Looking back on the patients whose records we have presented here, we regret that the treatment was applied so late to many of them, but the method was a new one in the hospital and only the most difficult cases were chosen for this series. Few who have seen the transformation epidural analgesia brings to a woman distressed with an incoordinate first stage can fail to welcome it with enthusiasm.

Incoordinate labour remains a major problem in modern obstetric practice. Caesarean section cuts across the problem but does not provide an answer to it. The ideal solution would be to achieve complete control over uterine function and complete pain relief at the same time. We do not claim that epidural analgesia does this, but it is a step towards the ideal.

Summary

One hundred women with incoordinate uterine action had labour managed under continuous epidural analgesia, the average duration of the block being 10 hours. Most of the patients were primigravidae, many were of small stature, and many had large babies, commonly with the occiput in the posterior position. Graphic analysis of labour showed an increased rate of cervical dilatation after epidural block in over 70%. The caesarean section rate remained high (55%) in cases complicated by mechanical dystocia, but where this was not present the caesarean section rate was much lower (14%), while in those patients who had no cephalopelvic disproportion and who showed an increased rate of dilatation after epidural block the caesarean section rate was only 3.8%. With this management, caesarean section is rarely required purely for incoordinate uterine action or maternal distress.

The perinatal mortality in the series was 2%, and there were no serious maternal complications.

Dr. John MacVicar provided the initial stimulus for this work, and our thanks are due to him and to Professor Ian Donald for continued encouragement and help. The work could not have been done without the untiring efforts of the labour room staff, whose cheerful co-operation was much appreciated.

Value of Rectal Biopsy in Paediatric Neurology: Report of 165 Biopsies

E. M. BRETT,* D.M., M.R.C.P. ; C. L. BERRY,† M.B., B.S.

Brit. med. J., 1967, **3**, 400–403

Biopsy of neural tissue, with subsequent histopathological, chemical, and histochemical examination, plays an important part in the investigation of suspected degenerative disease of the central nervous system in infancy and childhood. For a number of reasons brain biopsy is not always acceptable to parent or clinician.

The possibility of using rectal biopsy as a diagnostic test for progressive degenerative brain disease seems to have been first suggested by the necropsy observation of Globus (1942), who noted similar degenerative changes in neurones of the central nervous system and of the myenteric plexus in a case of amaurotic idiocy. Landing and Freiman (1957) encountered similar necropsy findings in various forms of amaurotic idiocy, Niemann–Pick's disease and Hurler's syndrome; and Nakai and Landing (1960) suggested that rectal biopsy might be used in the diagnosis of neurolipidosis. Kobayashi (1960) proposed the use of biopsy of the rectal wall or appendicectomy for the histochemical demonstration of "the dystrophic deposit in ganglion cells of the myenteric plexus" in gargoylism. A series of 75 rectal biopsies was reported by Martin, Landing, and Nakai (1963), but many of these were from patients with suspected Hirschsprung's disease or were incidental to operations for imperforate anus, and only 11 seem to have been intended primarily to further the neurological diagnosis. No specific neurological diagnoses were reached as a result of these biopsies, but the authors believed that rectal biopsy might be as reliable as brain biopsy in the neural lipidoses, and that it should probably be considered in the diagnostic investigation of any otherwise unexplained degenerative neurological disorder of childhood.

Bodian and Lake (1963) reviewed 21 necropsies in which complete agreement was found between neuronal changes in the central nervous system and in the gastrointestinal tract, and there was also evidence of metachromasia in the latter if present in the brain. They further reported a series of 49 rectal biopsies based on this study; 26 of these were normal and 23 showed abnormalities. The latter included 12 cases with changes regarded as non-specific, and 11 with diagnostic features (seven cases of neurolipidosis and four of metachromatic leucodystrophy. The authors suggested that this

investigation "embraces the spectrum of neurolipidosis, metachromatic leucoencephalopathy, and possibly sudanophilic leucodystrophy." They believed that these biopsies were far safer than brain biopsy and might well be obtained at an early stage of the evolution of the various diseases.

In subsequent years many more rectal biopsies have been performed at the Hospital for Sick Children, Great Ormond Street, and in this paper we review the results of 165 biopsies from 164 patients over the five-year period 1962–6. These include 47 of Bodian and Lake's series (but not the two performed at other hospitals) and 118 more recent biopsies.

Methods

Full-thickness rectal biopsies were performed under general anaesthesia. For the initial six months of the period considered, half the tissue obtained was fixed in buffered formalin and then sectioned on a freezing microtome. The remaining tissue from these biopsies and all later material was frozen on solid carbon dioxide. Sections measuring 5–7μ were then cut in a cryostat.

Specimens were stained by haematoxylin and eosin, periodic-acid Schiff (P.A.S.), Sudan black, scharlach red, luxol-fast blue, toluidine blue, cresyl-fast violet, Feyrter's thionine, and, where appropriate, a colloidal iron method for interstitial mucopolysaccharide (for details of methods see Bodian and Lake, 1963).

The sections were reviewed by one of us (C. L. B.) without knowledge of the clinical status of the patients. In a few cases review of the earlier sections has resulted in the original interpretation being altered in the light of subsequent histological experience.

Biopsies with Positive Diagnostic Abnormalities

Of the 165 biopsies 33 (20%) showed positive diagnostic features. The proportion of positive biopsies was 20% for children in the total group, 31% for those under the care of the neurological unit, and 13.5% for those in other wards.

Clinical Diagnosis in 33 Cases with Positive Biopsies.—Thirty of these, or approximately 90%, were from patients with neurolipidosis or metachromatic leucodystrophy, as in the initial series of Bodian and Lake. There were 19 cases of neurolipidosis and 11 of metachromatic leucodystrophy. Hurler's syndrome provided two cases, and there was one case of Niemann–Pick's disease.

Duration of Symptoms at Time of Biopsy.—In neurolipidosis it was less than one year in eight, one year in three, two years in three, three years in two, and four years or more in two. One case was of doubtful duration. Five of the eight cases diagnosed by biopsy after less than one year of symptoms were examples of Tay-Sachs disease. In the cases of metachromatic leucodystrophy the duration of symptoms was less than one year in three, two years in two, three years in two, and four years in three, one case being of uncertain duration.

Clinical Features of Cases with Positive Biopsies

A history of dementia or regression in psychomotor skills was the most prominent feature in the two major diseases, being present in 17 of the 19 cases of neurolipidosis and in 9 of the 11 cases of metachromatic leucodystrophy. Convulsions occurred in seven of the neurolipidosis cases. A family history of an affected sibling occurred in five cases of neurolipidosis with biopsies in two pairs of siblings, and in seven cases of metachromatic leucodystrophy, including three pairs of siblings. The family history was suggestive in one further case of metachromatic leucodystrophy—a child whose sibling had died with a progressive neurological condition but without necropsy.

Macular changes were recorded in seven patients with neurolipidosis, five of whom, regarded clinically as examples of Tay-Sachs disease, showed pathognomonic cherry-red spots, bilateral in four cases. Optic atrophy was noted in a further two patients in this group.

Specific features deserving comment in the 11 cases of metachromatic leucodystrophy include a history of ataxia in four patients. In three of these unsteadiness seems to have been the presenting symptom, preceding dementia, the ages of onset being 6, 11, and 16 months. This conforms to the recognized pattern of infantile form of metachromatic leucodystrophy (Allen, 1964).

The occurrence of convulsions in two siblings with metachromatic leucodystrophy was rather unexpected, since these are regarded as infrequent in this disease (Lyon, Arthuis, and Thieffry, 1961 ; Allen, 1964).

Ancillary investigations pointing to the diagnosis (later proved by biopsy) were most helpful in the 11 patients with metachromatic leucodystrophy. In these the urine showed intracellular metachromatic material in all the eight cases in which it was examined by the method of Lake (1965). The conduction velocity in peripheral nerves was measured in nine cases and found to be substantially decreased in eight ; seven of these were previously reported by Fullerton (1964). Cholecystography by the oral route was performed in one patient with positive urine and abnormal conduction velocity, and the gall bladder showed no concentration of dye.

Laboratory tests proved less helpful in the patients with neurolipidosis. In one recent case the serum fructose-1-phosphate aldolase was found to be deficient (0.3 unit per ml. of serum) (Profesor J. N. Cumings) ; the level of this enzyme has recently been reported to be abnormally low in Tay-Sachs disease (Volk, Aronson, and Saifer, 1964 ; Schneck, Maisel, and Volk, 1964), and its measurement has been suggested as a useful screening test for this condition.

Pneumoencephalography gave evidence of cerebral atrophy in five of the six cases of neurolipidosis in which it was performed. In the two cases of metachromatic leucodystrophy so investigated the results were normal. This, with the finding of cerebral atrophy in 23 of the 35 air encephalograms in patients whose rectal biopsies were normal or showed non-specific changes, suggests that air encephalography is *not* a particularly useful investigation in the selection of patients for rectal biopsy. The situation is different when a cerebral biopsy is considered ; this should be preceded by an air encephalogram in order to exclude a congenital cerebral malformation of a kind which might alter the prognosis and management of the patient.

Biopsies without Diagnostic Abnormalities

On review, 132 biopsies taken from 131 patients were thought to show no abnormality.

Analysis of the major clinical features of these cases shows that, in contrast to the cases with positive biopsies, amentia or very early retardation with or without convulsions was the most frequent feature, occurring in 67 cases. Dementia occurred in only 29 cases, roughly one-fifth of the total. There were 15 patients with infantile spasms and 11 with autistic or psychotic features. In five cases without dementia or epilepsy the indication for biopsy was a family history suggesting a progressive cerebral degeneration or the finding of macular changes raising the possibility of such a condition. There were three patients with epilepsy alone and one in whom acute transient deterioration accompanied the sudden onset of epilepsy.

Biopsies with Non-specific Abnormalities

Fourteen of the 132 non-diagnostic biopsies, taken from 13 patients, were on review thought to show non-specific degenerative changes. These are listed below.[1] One patient, a boy with mental and neurological deterioration in association with intractable epilepsy, had two biopsies performed at an interval of 14 months, and similar non-specific abnormalities were seen in both. Nine of the 12 biopsies reported by Bodian and Lake as showing non-specific degenerative changes were thought on review to be within normal limits.

Analysis of the clinical features of the 13 patients with non-specifically abnormal biopsies shows that there were six with dementia and six with amentia. This contrasts with the predominance of dementia in the cases with positive (diagnostic) biopsies and with that of amentia in those with "negative" biopsies. Epilepsy was prominent in the histories of these patients, occurring in 61%, whereas it occurred in 27% of those with positive and 37% (excluding infantile spasms) of those with negative biopsies. The epilepsy was severe and intractable in many patients in this group, and the non-specific changes seen in their biopsies may perhaps reflect anoxia or other secondary effects of uncontrolled fits over long periods rather than any underlying primary degenerative disease.

Confirmation by Cerebral Biopsy or Necropsy

There were 13 cases in which, usually during the same hospital admission, both rectal and cerebral biopsies were carried out, the rectal usually preceding the cerebral biopsy. In six cases both biopsies were normal. Six patients, four with neurolipidosis and two with metachromatic leucodystrophy, showed diagnostic abnormalities in both biopsies. In one patient with subacute sclerosing leucoencephalitis cerebral biopsy showed diagnostic features of this disease, whereas rectal biopsy was normal.

Adequate necropsy studies are known so far to have been made in only seven patients with diagnostic rectal biopsies. These confirmed the diagnosis, in three cases of neurolipidosis and in four of metachromatic leucodystrophy, made on rectal biopsy. No post-mortem studies are so far known to have been made on patients whose rectal biopsies were normal or non-specifically abnormal.

Morbidity

The only complication encountered with any frequency in this series was rectal haemorrhage, which occurred in 13 cases (8%). Haematoma formation was seen in three patients and required drainage. Five patients needed blood transfusion post-operatively.

Discussion

In this series most of the positive rectal biopsies were from patients with neurolipidosis or metachromatic leucodystrophy. The successful selection of cases for such biopsies would therefore seem largely to depend on a high clinical likelihood of one of these specific diagnoses.

There were clear pointers, clinically or on investigation, to the diagnosis in 11 of the 19 neurolipidosis patients; these included macular changes, a family history of an affected sibling, and deficiency of serum fructose-1-phosphate aldolase. In the other eight patients, all of whom were demented, there were no clear indications, though one showed an exaggerated startle response to sound as described in Tay–Sachs's disease (Schneck *et al.*, 1964).

All 11 patients with metachromatic leucodystrophy showed clear evidence of the disease on investigation by urine examination alone (three cases), nerve-conduction studies alone (three cases), or both (five cases). In one patient with normal conduction velocity the urine contained intracellular metachromatic material. Thus the two tests complemented each other in this series. In the metachromatic leucodystrophy patients biopsy was in fact often used as a *confirmatory* investigation, and it could be argued that its use was unjustified in some cases. With the diagnostic help now available from laboratory investigations in this condition and likely to increase with the wider use of urinary sulphatase estimations (Austin *et al.*, 1964, 1966), biopsy, whether of rectum, brain, nerve, skin, or dental pulp (Gardner and Zeman, 1965), may well become obsolete. If biopsy is thought necessary when metachromatic leucodystrophy is strongly suspected, it would seem logical to biopsy a peripheral nerve as originally suggested by Thieffry and Lyon (1959); particularly if nerve-conduction velocity is slowed, rather than rectum or brain. In metachromatic leucodystrophy rectal biopsy is of value solely in showing changes in nerve *fibres*, and the same is true of appendix and dental pulp biopsy. Yudell *et al.* (1967) at the Mayo Clinic have now discontinued the use of rectal biopsy in metachromatic leucodystrophy in favour of biopsy of the sural nerve, which has so far given no false-negative results.

Diagnostic doubt in the neurolipidosis patients was least among those with Tay-Sachs disease because of the characteristic picture. For this group also, serum enzyme studies may well prove to be very reliable. With other forms of neurolipidosis clinical certainty is usually less, macular changes being less frequent and specific, and it is in this group that biopsy is likely to continue to be necessary, though improved chemical and electroencephalographic methods may in time provide tests of diagnostic reliability.

We cannot comment on the suggestion of Bodian and Lake that rectal biopsy might be of diagnostic value in sudanophilic leucodystrophy, since no cases have been investigated by it at this hospital. In this condition it would seem reasonable to prefer cerebral to rectal biopsy until such time as diagnostic changes have been found in the myenteric plexuses in cases at necropsy.

Rectal biopsy was negative in one patient with subacute sclerosing leucoencephalitis in whom brain biopsy was diagnostic. This boy was Case 8 in Bodian and Lake's series of cases with pathological changes other than neurolipidosis or metachromasia, two P.A.S.-positive cytoplasmic inclusions in rectal neurones being mentioned. This finding is quoted by Paine and Oppé (1966), but the inclusions seen in the rectal biopsy were not in fact typical of those seen in subacute sclerosing encephalitis, and similar inclusions have since been seen in a small number of rectal biopsies from patients not suffering from this condition.

Summary

A series of 165 rectal biopsies performed in conditions other than Hirschsprung's disease at the Hospital for Sick Children, Great Ormond Street, in the five years 1962–6, is reviewed. Thirty-three of these biopsies (20%) showed diagnostic and 14 non-specific abnormalities, 118 being normal. Neurolipidosis and metachromatic leucodystrophy were diagnosed on 30 of the positive biopsies. The clinical features of the positive, "negative," and non-specific abnormal groups are reviewed. It is concluded that rectal biopsy is of particular value in the diagnosis of neurolipidosis and metachromatic leucodystrophy. However, it is suggested that where adequate laboratory facilities exist biopsy in the latter condition may become unnecessary

---

[1] Non-specific degenerative changes included a variable degree of distension of neurones with cytoplasmic granularity, increased eosinophilia, and occasionally vacuolation with no specific histochemical staining reaction. Nuclear changes, including condensation of chromatin around the nucleolus with a ballooned appearance of the remainder of the nucleus, were often present.

The presence of P.A.S.-positive macrophages in the lamina propria has been reported as a non-specific abnormality, but this change, together with those already described, has been seen in cases of chronic constipation, megacolon, epilepsy, fibrocystic disease, Hirschsprung's disease, etc.

and that increasing refinement of chemical and other investigations may in time render biopsy obsolete also in many cases of neurolipidosis.

Pneumoencephalography was of no value in selecting cases for rectal biopsy, since it showed cerebral atrophy with equal frequency in patients whose biopsies later did and did not show diagnostic changes.

No diagnostic abnormalities were found on rectal biopsy in patients without dementia, a positive family history of relevant disease or other features pointing strongly towards a specific neurological condition.

We thank the physicians and surgeons of the Hospital for Sick Children, Great Ormond Street, for permission to publish details of patients in their care.

Effect of Total Dose Infusion of Iron-dextran on Iron, Folate, and Vitamin B_{12} Nutrition in Postpartum Anaemia

J. METZ,* M.D., M.C.PATH.; T. EDELSTEIN,* M.B., DIP.O.&G.; M. DIVARIS,* MED.TECH.; S. S. ZAIL,* M.D.

Brit. med. J., 1967, 3, 403–406

The efficacy of total dose infusion of iron-dextran (T.D.I. Imferon) in the treatment of antepartum and postpartum iron-deficiency anaemia is well established (Varde, 1964; Basu, 1965; Bonnar, 1965). Detailed studies on the effect of T.D.I. Imferon therapy on the iron, folate, and vitamin B_{12} nutritional status of iron-deficient women have, however, not yet been reported. Such information is necessary in view of the poor response to T.D.I. Imferon noted in folate-deficient women (Basu, 1965; Bonnar, 1965), and the suggestion that reactions to T.D.I. Imferon may be related to folate deficiency (Clay *et al.*, 1965; Lane and Scott, 1965). In the present study comprehensive tests of iron, folate, and vitamin B_{12} nutrition were carried out before and after administration of T.D.I. Imferon therapy to postpartum anaemic subjects. This therapy generally resulted in restoration of normal nutrition, but the postpartum improvement in folate nutrition, shown in untreated control subjects, was retarded.

Material and Methods

All subjects were Bantu admitted to Baragwanath Hospital, Johannesburg (altitude 5,760 ft.; 1,756 m.). Consecutive patients with haemoglobin levels of less than 10 g./100 ml. and decreased marrow iron stores on the third postpartum day were included in the study. A total of 81 patients received T.D.I. Imferon, and 61 of them returned for follow-up six weeks later; 12 of these 61 received folic acid as well as Imferon. Control subjects consisted of 18 patients who received no therapy. The control group is much smaller than the group receiving therapy, for during the course of the study pronounced differences between the groups became apparent, and it was not felt warranted to leave more patients untreated.

Procedure

Before therapy on the third postpartum day venous blood was drawn for measurement of haemoglobin, haematocrit, serum iron, unsaturated iron-binding capacity (U.I.B.C.), serum folate activity, serum vitamin-B_{12} concentration, and for the preparation of films. Blood for serum iron and U.I.B.C. estimation was allowed to drip direct from the needle into iron-free containers. Films were prepared from bone marrow aspirated from the sternum.

Imferon was administered as follows. The dose for each patient was calculated as described by the manufacturers. The Imferon was diluted in normal saline, not more than 20 ml. being added to a litre of saline. The infusion was started at 10–15 drops a minute until 100 ml. had been administered, and thereafter at 45 drops a minute. Before infusion basal readings of the pulse and blood pressure were made, and these were repeated at hourly intervals during the infusion. Any untoward symptoms occurring during the infusion were recorded. Forty-eight hours after completion of the infusion the site was examined for pain, tenderness, swelling, and redness, and the lower limbs were examined for evidence of venous thrombosis. The 14 patients who were to receive folic acid were then given folic acid tablets (5 mg.) and instructed to take at least one tablet daily for a period of 40 days.

The patients were studied again six weeks later. All previous investigations, including bone-marrow-puncture, were repeated. Patients were re-examined for symptoms or signs of venous thrombosis at the site of infusion and in the legs. After withdrawal of the blood and marrow samples the investigation of the patients was complete; those who had received only Imferon therapy were supplied with folic acid tablets, and those who had received no therapy since delivery were treated with iron and folic acid by mouth.

Laboratory Methods

Haemoglobin was estimated as cyanmethaemoglobin, a commercially obtained standard being used. The haematocrit was

---

* Department of Haematology, South African Institute for Medical Research, and Department of Obstetrics, Baragwanath Hospital, Johannesburg.

measured in a microhaematocrit centrifuge, and the mean corpuscular haemoglobin concentration (M.C.H.C.) calculated in the usual way. Serum iron and unsaturated iron-binding capacity were measured by the methods of Bothwell and Mallett (1955) and Charlton *et al.* (1965) respectively. Serum vitamin B_{12} was assayed with *Lactobacillus leichmannii* (Brandt and Metz, 1961) and serum folate activity with *L. casei* (Herbert, 1961; Waters and Mollin, 1961). Blood films were stained with Wright's stain and examined for hypochromia, and for hypersegmented neutrophils. When more than 3% of the neutrophils showed five or more lobes in the nucleus, a "shift to the right" was regarded as being present. Wright's stained bone-marrow films were examined for the presence of megaloblasts and giant myeloid cells. In addition, marrow films were stained for haemosiderin by the Prussian-blue reaction, and iron stores in the particles graded from 0 to +6. Grades +3 and +4 were regarded as normal, grades +5 and +6 as excessive, and grades 0 to +2 as diminished iron stores. In grade 0 no stainable iron was observed; in grade +1 stainable iron was just visible in one or two particles, and in grade +2 stainable iron was just visible in several particles. Only subjects with marrow iron stores in grades 0 to +2 were included in the study.

Results

In comparing the results obtained at the first and final assessments of the patients studied, only paired observations were used. Thus if a particular index was not available in a patient at the first assessment—for technical reasons, for example—it was excluded from the second assessment, and vice versa.

The mean values for haemoglobin, haematocrit, M.C.H.C., serum iron, U.I.B.C., serum folate, and vitamin B_{12} before and after therapy in patients receiving Imferon without added folic acid are shown in Table I. The iron stores are shown in Fig. 1, and the incidence of right shift, megaloblasts, and giant myeloid cells in Fig. 2. There was a marked rise in the mean haemoglobin, haematocrit, serum iron, and percentage saturation and a fall in U.I.B.C. values; the differences in the mean values were all statistically significant (Table II). In no patient after treatment was the haemoglobin value less than 11 g./100 ml. There was a rise of 0.41% in the mean value for the M.C.H.C., but this difference is not statistically significant. There was also little change in the percentage of subjects showing hypochromia (40% at delivery, 36% six weeks later), but the degree of hypochromia was invariably less at six weeks. There was an increase in iron stores in all patients after Imferon therapy.

The mean serum folate activity after Imferon showed little change to the pretherapy level, the difference in the mean values not being statistically significant (Table II). That folate nutri-

tion was not obviously improved after Imferon was further reflected in the constant number of subjects who showed megaloblastic change in the marrow before and after therapy. There was, however, a moderate fall in the number of subjects who showed a right shift in the neutrophils and giant myeloid cells in the marrow. The mean serum vitamin-B_{12} concentration after Imferon was higher than the pretreatment level, but the difference is not statistically significant.

The mean values of the various haematological indices and the indices of iron, folate, and vitamin B_{12} nutrition at the first and final assessment in the group who received no therapy are shown in Tables I and II and Figs. 1 and 2. Six weeks after delivery these subjects also showed a marked rise in haemoglobin and haematocrit, the differences in the mean values being statistically significant. In four of the 21 subjects (19%), however, the haemoglobin value was less than 11 g./100 ml. and in two of these it was less than 10 g./100 ml. The mean serum iron level also rose, but in contrast to the patients who received Imferon the U.I.B.C. rose markedly, so that the mean percentage saturation of transferrin showed little change after six weeks. The striking difference in percentage saturation of transferrin between the control and Imferon-treated group was further reflected in the iron stores. In patients who had no stainable iron in the marrow after delivery the particles remained free of demonstrable iron six weeks later. In all but two of the patients with some stainable iron after delivery no iron could be found six weeks later. In these two patients some iron remained in the particles, but a smaller amount than at delivery. There was also a striking increase both in the incidence (10% at delivery and 66% six weeks later) and the degree of hypochromia in this group after six weeks.

In contrast to the group who received Imferon (without folic acid), the control group showed a statistically highly significant rise in mean serum folate levels after six weeks. This improvement in folate nutrition was reflected in the virtual disappearance of megaloblastic change in the marrow. The incidence of giant myeloid cells in the marrow and right shift in the neutrophils also fell, but in many patients these changes were still present six weeks post partum. The mean serum vitamin-B_{12} concentration was slightly lower after six weeks, but the difference is not statistically significant.

The mean values of the various haematological indices and tests of iron, folate, and vitamin B_{12} nutrition in the subjects who received Imferon and folic acid are shown in Tables I and II and Figs. 1 and 2. After treatment with Imferon and folic acid these subjects showed highly significant rises in haemoglobin, haematocrit, serum iron, and percentage saturation, and a fall in U.I.B.C. as observed in the group who received Imferon alone. The mean rise in haemoglobin levels was greater than in the group who received Imferon alone. Iron stores increased in all subjects. The mean serum folate levels showed a marked rise, and morphological evidence of folate deficiency was much less apparent than in the subjects who received only Imferon. The mean serum vitamin-B_{12} concentration was higher after six weeks, but the difference is not statistically significant.

Reactions in Those Having Total Dose Imferon Infusions

Of the 81 patients who received Imferon, five (6.2%) developed thrombophlebitis at the site of the infusion within 48 hours. Two patients also complained of headache during the infusion, but the infusions were completed without further ill-effect. Two patients complained of pain in the arm at the site of the infusion during the administration of the Imferon, but did not develop any evidence of thrombophlebitis. One patient, not included in the series, had an attack of shivering soon after the start of the infusion, but there was no fall in blood pressure or rise in pulse rate. This infusion was immediately discontinued. Major anaphylactic reactions were not encountered.

Compared with the rest of the group there was no obvious difference in the folate nutrition, as determined by serum folate levels and blood and bone-marrow changes, in the patients who showed any form of reaction.

Discussion

The value of intravenous infusion of Imferon has been well substantiated as a rapid means of correcting anaemia in late pregnancy. In a recent study Bonnar (1965) has also demonstrated its effectiveness in correcting anaemia after abortion and in postnatal blood-loss anaemia. In the present study of iron-deficient postpartum anaemia, a mean rise in haemoglobin of 4.15 g./100 ml. was obtained in six weeks in the group receiving Imferon alone. This was greater than the rise obtained in the control group (3.14 g./100 ml.) but not as great as that (4.73 g./100 ml.) in the group receiving folic acid in addition to T.D.I. Imferon. These changes were reflected in the haematocrit values after six weeks. It is thus apparent that iron-deficient postpartum patients can spontaneously correct their haemoglobin levels almost to those found in the subjects given iron therapy. However, the rise in haemoglobin levels in the group of untreated women often failed to reach normal values, and was invariably associated with deterioration in their already precarious iron nutrition. What little iron was present in the marrow particles usually disappeared, hypochromia became more marked, and the percentage saturation of transferrin failed to rise. By way of contrast, in patients who received T.D.I. Imferon therapy iron stores increased markedly, hypochromia decreased, and the percentage saturation of transferrin more than doubled.

The effect of parenteral iron therapy on folate nutrition in pregnancy has been referred to by previous workers. Bonnar (1965) noted that in antenatal patients who received intravenous Imferon, 20% developed signs of an unsuspected folate deficiency which resulted in an impaired response to the iron therapy. Similar findings have been reported by Scott (1963) in a comparable group treated with intramuscular iron. She suggested that the earlier diagnosis of folate deficiency rather than any specific effect of the parenteral iron accounted for this high incidence. However, a recent study by Combrink *et al.* (1966) indicated that parenteral iron therapy itself in antenatal anaemic women may lead to signs of folate deficiency. The administration of folic acid with T.D.I. Imferon therapy will prevent this complication (Varde, 1964 ; Goldthorp *et al.*, 1965).

The results of the present study provide further evidence for a direct effect of parenteral iron therapy on folate nutrition in anaemias associated with pregnancy. In untreated subjects there was marked improvement in the indices of folate nutrition in the six-week period after confinement. This improvement was negligible in patients who received Imferon, the serum folate levels and the incidence of bone marrow megaloblastic change being similar before and after treatment. Addition of folic acid to Imferon therapy resulted in high serum folate levels and disappearance of megaloblasts from the marrow. The mechanism whereby parenteral iron retards improvement in folate nutrition is unknown. It is probably related to increased utilization of haemopoietic factors following on intense stimulation of erythropoiesis due to rapid replenishment of iron stores in the iron-deficient patient. These findings also substantiate the recommendation to administer folic acid routinely with Imferon infusion (Varde, 1964 ; Goldthorp *et al.*, 1965).

The observed changes in serum vitamin-B_{12} concentrations were relatively small. Compared with delivery, the mean values at six weeks were higher in patients who received T.D.I. Imferon and lower in the control group. There was, however, considerable variation in individual levels within the groups, and the observed differences in the mean values are not statistically significant. The results of the present study do not suggest any consistent effect of T.D.I. Imferon therapy on vitamin B_{12} nutrition.

Though most of the subjects in the present study showed evidence of folate deficiency, no major reaction to T.D.I. Imferon therapy was encountered in a total of 81 infusions. This finding does not substantiate the suggestion that major reactions may be related to folate deficiency (Lane and Scott, 1965). Thrombophlebitis at the site of infusion occurred in five patients; it was not related to the use of 5% dextrose water as diluent for the Imferon, as only normal saline was used. The slow rate of infusion may possibly have been a factor in producing thrombophlebitis.

Summary

Iron-dextran by the total dose infusion technique was administered to 81 postpartum anaemic subjects with diminished marrow iron stores. Tests of iron, folate, and vitamin B_{12} nutrition were carried out before therapy and repeated six weeks later.

Iron-dextran therapy was regarded as satisfactory in that anaemia was corrected and tests of iron nutrition returned to normal. In untreated control subjects anaemia was often spontaneously corrected, but this was accompanied by deterioration in iron nutrition.

Iron-dextran therapy retarded the improvement in tests of folate nutrition after confinement which occurred in untreated subjects. This substantiates the recommendation that folic acid be administered routinely to patients receiving Imferon therapy for anaemia associated with pregnancy.

No consistent effect of iron-dextran therapy on vitamin B_{12} nutrition could be shown.

We wish to thank the Director, South African Institute for Medical Research, and the Superintendent, Baragwanath Hospital, Johannesburg, for facilities to carry out this study; Dr. D. Lavery and Dr. R. Cassel for their help; Mrs. J. Oshry and Mrs. G. Bird for technical assistance; Sister M. Johnstone and the nursing staff at Baragwanath Hospital for their enthusiastic co-operation; and Fisons Chemicals (S.A.) (Pty.) Limited for supplies of Imferon. This study was supported in part by a research grant from the World Health Organization.

Influenza in the West of Scotland, 1966

J. C. TAYLOR,* M.R.C.P.GLASG.; CONSTANCE A. C. ROSS,† M.D., M.C.PATH.; E. J. STOTT,†‡ B.A.

Brit. med. J., 1967, **3,** 406–408

The west of Scotland experienced concurrent epidemics of influenza type A and type B in the first quarter of 1966. The present study describes virological and clinical findings in 119 cases diagnosed as influenza by the Regional Virus Laboratory, Ruchill Hospital. Four cases of encephalitis associated with one particular age group are also reported.

Materials and Methods

During the epidemics tests for influenza-A and for influenza-B infections were carried out on routine specimens received by the laboratory from patients either in hospital or at home. The patients investigated comprised not only those with influenzal symptoms but also those with infections of the upper and lower respiratory tracts or other pyrexial illnesses for which no other cause could be found. From most of the children only specimens for virus isolation were obtained because of the difficulty of obtaining sera. In contrast, from most of the adults sera only were collected because of limited laboratory resources for isolation of respiratory viruses.

Virus Isolation.—Specimens for virus isolation comprised swabs of throat or throat and nose. Each swab (cotton-wool on wooden shaft) at collection was broken into 2 ml. of transport medium (Grist *et al.*, 1966). Of each extract 0.2 ml. was inoculated into one tube of secondary rhesus monkey kidney tissue culture, which was examined and maintained as described by Grist *et al.* (1966). Growth of either influenza-A (three strains) or influenza-B (23 strains) produced haemadsorption and generally also cytopathogenic effect in three to seven days. The type of influenza was determined by complement-fixation tests against both influenza-A and influenza-B human convalescent sera. Influenza complement-fixing antigen was usually detected at the fifth to eighth day in the primary culture; the remaining strains all fixed complement in the first passage, antigen titres ranging from 2 to 32 for the type B strains and being 32 for all three type A strains. Titres of influenza-B haemagglutinin varied from <4 to 128 in the primary culture and from 8 to 256 in the first pass; titres of influenza-A haemagglutinin were lower, being <4 in the primary culture and not above 8 after two passes. Representative type A and type B strains from children and adults were sent to Dr. H. G. Pereira, W.H.O. Influenza Centre, London, who reported that they were antigenically similar to recently isolated type A and B strains.

Serology.—Paired sera were examined for complement-fixing antibodies against influenza-A and influenza-B soluble antigens and against other relevant viral antigens as described by Grist *et al.* (1966). As the optimal concentrations of both influenza antigens were generally twofold to eightfold greater for young children than for older children or adults, two doses of each antigen were used: the higher concentration for testing sera from children under 6 years of age, and a four times lower concentration for sera from older children and adults. All titres in this paper are expressed as reciprocals.

‡ Present address: Common Cold Research Unit, Harvard Hospital, Salisbury, Wilts.

Virological Findings

The criteria accepted as evidence of infection with influenza-A or influenza-B were virus isolation and/or positive serological findings comprising a fourfold or greater rise in titre, a high but not rising titre ($\geqslant 256$), or a fourfold or greater fall in titre.

Infection with influenza type A or type B was detected in 119 cases—61 due to type A and 58 to type B (Table I). A surprising finding was the complete absence of type A infections in the children aged 6 to 15 years, contrasting with the large number of type B infections. This suggested that children aged 6 to 15 had a high level of immunity against type A_2, the current infecting type A strain in Britain since 1957, but were susceptible to type B infection. In patients under 6 and over 15 years type A was diagnosed more frequently than type B infection.

TABLE I.—*Number of Cases with Influenza in Relation to Age*

Influenza	Age Group (Years)						Total Cases
	0–5	6–10	11–15	16–20	21–50	50+	
Type A ..	9	0	0	7	12	33	61
„ B ..	7	18	9	2	10	12	58
Total cases ..	16	18	9	9	22	45	119

Comparison of Virus Isolation and Serology.—Specimens for both virus isolation and serology were received from only 18 of the 119 influenza patients. Though the numbers are small the results shown in Table II suggest that at ages of over 5 years serological diagnosis by complement fixation was more reliable than virus isolation. In contrast, of the three children under 3 years of age from whom virus was isolated, only one showed a complement-fixing antibody response.

TABLE II.—*Comparison of Virus Isolation and Serology*

Age in Years	No. of Cases	Virology		
		VI+. S+	VI+. S−	S+. VI−
Under 3 ..	3 (1)	1 (1)	2	0
6–15	6	3	0	3
Over 15 ..	9 (4)	7 (2)	0	2 (2)
Total ..	18 (5)	11 (3)	2	5 (2)

Figures in parentheses indicate number of type A cases; others were type B. VI+ = Influenza virus isolation positive. VI− = Influenza virus isolation negative. S+ = Influenza serology position. S− = Influenza serology negative.

Complement-fixing Antibody Response and Age.—Previous workers have shown that the complement-fixing antibody response to soluble antigen is poor in young children with influenza (Grist, 1957; Henle and Lief, 1960). This was confirmed in the present study. Thus, of 60 patients in whom a rise in antibody titre and/or positive virus isolation had been demonstrated, titres greater than 32 were obtained in 36 out of 41 over 15 years of age, in three out of five aged 6 to 15 years, but in none of 14 children under 6 years old.

Clinical Features

The presenting clinical diagnoses in the 88 patients admitted to hospitals are listed in Table III in order of frequency. These patients probably represent the most severe clinical illnesses and complications in the various age groups. Pneumonia was found in all four age groups but was less common in children under 6 years than in the other groups. Influenza was not diagnosed in any of the children under 6 years. The diagnoses which were particularly associated with specific age groups were: croup in the children under 6 years (four of the five cases being under 3 years), encephalitis in those aged 6 to 15 (all four cases being from 6 to 10 years), and acute exacerbations of chronic bronchitis in those over 50.

TABLE III.—*Presenting Clinical Diagnosis in* 88 *Hospital Patients with Influenza*

Diagnosis	Age Group (Years)				Total Diagnoses
	Under 6	6–15	16–50	Over 50

Total patients	16	17	19	36	88

Encephalitis

As the children with encephalitis showed severe neurological involvement their case histories are given below.

Case 1.—A girl aged 6 years had a fatal illness. On 21 February 1966 she developed sore throat, fever, and cough. Three days later her behaviour became abnormal. On admission to another hospital she was semiconscious, reflexes were brisk, and the plantar reflexes were extensor. Over the next two days she became unconscious. On admission to Ruchill her temperature was 101.6° F. (38.7° C.). The tendon reflexes were now absent and the plantar reflexes were extensor. The pupils did not react to light. She was cyanosed and had bulbar paralysis. She died on 28 February, the eighth day of illness. At necropsy the striking feature was marked swelling of the brain due to oedema, but there was no coning. Microscopical examination showed no demyelinization.

Case 2.—A girl of 6 years developed coryza and cough on 19 January 1966. Four days later she was found unconscious. On admission to Ruchill on the sixth day of illness she was in coma. There was nuchal rigidity; the tendon reflexes were present, the plantar reflexes were flexor, and the pupils reacted normally. There were occasional purposeless movements of the arms and trunk but no true convulsions. The temperature was 100.6° F. (38.1° C.). Improvement was apparent four days after onset of coma. Recovery was complete when discharged on 12 February.

Case 3.—A girl of 8 years developed coryza, cough, and vomiting on 25 January 1966. She improved, but after seven days vomiting and cough returned and she talked nonsense. On the ninth day she became unresponsive to stimuli. There were no convulsions. On admission to Ruchill on 4 February her temperature was 101° F. (38.3° C.). Consciousness varied from stupor to coma; reflexes were depressed, muscle tone was low, but the plantars were flexor. The pupils reacted normally and meningism was absent. There were occasional purposeless movements of the upper limbs. Recovery took place very slowly: she began to respond to orders six days from loss of consciousness, but it was another 10 days before her mentality appeared normal. Ultimately recovery was complete.

Case 4.—A boy of 9 years was admitted to hospital on 15 January 1966 after five days' coryza and cough and one day's twitching and incontinence of urine. On admission his temperature was 100.4° F. (38° C.). The tonsils and pharynx were inflamed and the lips were blistered. He had several convulsions in which his gaze deviated to the right, but the convulsive movements were mainly of the left side of his body. Next day he was found to have a left monoparesis of the arm, his left plantar reflex was extensor, and he was in coma. He was transferred to a neurological unit for further investigations. Convulsions ceased 48 hours after onset of nervous symptoms. Right carotid angiography was negative and his left monoparesis was improving when he was returned to Ruchill on the 12th day of illness. Recovery was complete when discharged on 28 March.

Laboratory Findings.—The relevant laboratory findings in the four cases of encephalitis are shown in Table IV. Cerebrospinal fluid showed an increase in cells and/or protein in Case 2 only;

this was the only patient with clinical evidence of meningeal irritation. Evidence of active or recent infection with influenza-B virus was obtained in all cases. The isolation of influenza-B from Cases 1 and 4 and absence of detectable antibody in their "acute" sera indicated that in these two cases the onset of encephalitis occurred early in the illness. However, it was of interest that Case 1 also showed evidence of recent infection with respiratory syncytial virus (high but not rising titres) and Case 4 had an active concurrent infection with herpes simplex (virus isolation and a rising titre). In contrast, failure to isolate influenza virus from Cases 2 and 3 along with high but not rising titres to this virus indicated onset of encephalitis late in the illness.

TABLE IV.—*Laboratory Findings in Encephalitis Cases*

Case	Age in Years	Cerebrospinal Fluid (per ml.)			Virus Isolations (Throat and Nose Swabs)	Serum	
		Cells	Protein	Sugar		Day of Illness Acute/conv.	Influenza-B C.F. Titres Acute/conv.
1	6	5	15	65	Influenza-B	7/ND	[*] <8/ND
2	6	30	60	68	Negative	6/21	256/256
3	8	1	20	71	Negative	11/22	512/128
4	9	1	20	79	Influenza-B. Herpes simplex	5/17	<8/16[†]

[*] Also high titre (512) for respiratory syncytial virus.
[†] Rising titre for herpes simplex (64/256) also obtained.
ND = Not done as patient died.

Discussion

Previous studies, such as those described in the Report of the M.R.C. Working Party on Acute Respiratory Virus Infections (1965), have shown that the clinical picture of influenza and its complications may be very variable, being more frequently atypical at the extremes of life. In young children influenza is generally a mild illness and respiratory complications are rare. The present study has confirmed the variability of the clinical picture, particularly as seen in young children. Though croup was the commonest presenting diagnosis in those under 6 years of age in hospital, none required tracheostomy. In the hospital patients over 50 years old respiratory complications were frequent, the majority presenting with pneumonia or an acute exacerbation of chronic bronchitis; these are well-recognized complications of influenza in older patients (Stuart-Harris, 1966).

Development of encephalitis early and late in the influenzal illness has been described by Hoult and Flewett (1960), who suggested that in the early type of encephalitis in which histological lesions were minimal the damage might be caused by toxin or by actual virus multiplication, and that the late type showing perivascular demyelination might be produced by anti-brain antibodies. In the four cases described in the present study virological findings suggested that encephalitis developed early in the influenzal illness in two and late in the other two. Of the two early cases the patient who died (Case 1) showed serological evidence of recent infection with respiratory syncytial virus; this may have accounted for the severity of the ensuing influenzal infection. The other patient (Case 4) had a concurrent infection with herpes simplex, so it is uncertain whether influenza-B or herpes simplex or a synergic effect of both viruses caused the encephalitis.

All four patients with encephalitis in the present series were aged 6 to 10 years; the absence of this complication in the younger and older age groups is surprising. A possible explanation is that the patients aged 6 to 10 years had the greatest number of type B infections, many of which were probably primary. However, the absence of encephalitis in those under 6 years, in whom there would be an even higher proportion of both type A and type B primary infections, suggests that some other factor relevant to age was related to the onset of encephalitis. In this connexion the poor antibody response of young children to influenza might be relevant, as development of the late type of encephalitis might require both a primary infection and a good antibody response. The poor antibody response of young children might protect them against the type of encephalitis which Webb and Smith (1966) have suggested may be associated with an antigen-antibody reaction. If this type of reaction is concerned in the late type of influenza encephalitis then the age incidence of this complication might depend on the peak age incidence (excluding very young children) of primary infection with influenza; this would vary from epidemic to epidemic, depending on the community's previous experience of the infecting influenza strain or antigenically related strains. To establish a correlation between encephalitis and primary infection detailed serological surveys of influenza antibodies in different age groups of the community would be required. As such surveys had not been done in this area before the present epidemics, further investigations along these lines are indicated.

Summary

During the first quarter of 1966 there were concurrent epidemics of influenza type A and type B in the Glasgow area. Virological diagnosis of active infection with type A was made in 61 patients and of type B in 58. Type A infections were more frequent than type B in patients under 6 years and in those over 15 years. In children aged 6 to 15 years no type A but a large number of type B infections were detected. This suggested that children aged 6 to 15 years had high immunity against type A_2, the current infecting type A strain in Britain since 1957, but were susceptible to type B infections.

In 88 patients admitted to hospital the clinical diagnoses particularly associated with specific age groups were: croup in children under 6 years old, encephalitis in those aged 6 to 10, and acute exacerbations of chronic bronchitis in patients over 50. The four encephalitis cases are described and possible reasons for development of this complication are discussed.

We are grateful to the many doctors in hospital, public health, and general practice (particularly Drs. W. Blair and A. Clarke) who sent us specimens; and to Professor T. Anderson and Dr. I. W. Pinkerton for permission to publish details of the encephalitis cases. We thank Dr. H. G. Pereira, W.H.O. Influenza Centre, Mill Hill, London, for antigenic analysis of influenza strains, Dr. J. F. Boyd for necropsy findings, and Mr. S. McMichael, A.I.M.L.T., and Miss M. Walker for valuable technical assistance.

Comparison of Duration of Activity of Corticotrophin-Gelatin and Corticotrophin-Carboxymethylcellulose

M. FRIEDMAN,* M.D., M.R.C.P.ED.

Brit. med. J., 1967, 3, 409–410

Corticotrophin is rapidly destroyed in the blood stream. Several substances have been added to corticotrophin in order to prolong its duration of action. These substances act at the site of injection and delay the release or destruction of corticotrophin. In the United Kingdom gelatin and zinc preparations of corticotrophin have been in use for many years. Recently a preparation of corticotrophin with the addition of carboxymethylcellulose (Crooks A.C.T.H./c.m.c.) has been introduced in this country. The manufacturers have claimed that this preparation "lasts like" the gelatin preparation. An investigation has been undertaken in normal healthy volunteers to test the validity of this claim.

Methods

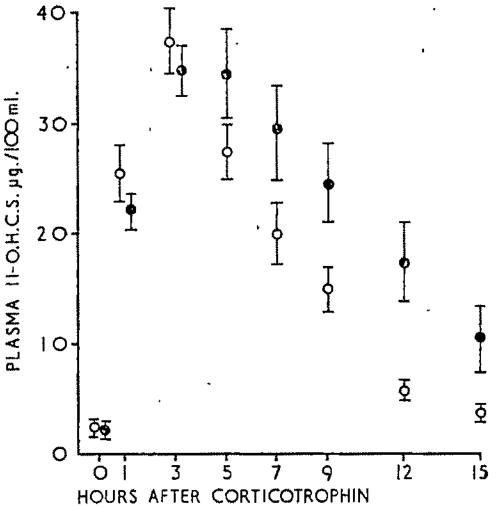
The investigation was carried out on 10 normal healthy volunteer subjects (two women and eight men) aged 22 to 35 years. They continued with their normal activities; there were no restrictions on diet or activity during investigation. Each subject was given 2 mg. of dexamethasone daily in four divided doses on the two days preceding the test and on the day of the test to suppress endogenous corticotrophin release. At 09.00 hours on the day of the test each subject was given either 40 international units of a gelatin-corticotrophin preparation (Acthar Gel Armour Batch No. KG. 2802) or 40 international units of corticotrophin-carboxymethylcellulose preparation (Crooks A.C.T.H./c.m.c. Batch No. 65091) by deep intramuscular injection. After an interval of seven days a second test was carried out under identical conditions administering the corticotrophin preparation not received in the first test. The initial preparation used in each subject was randomly selected. Blood samples were taken before and at 1, 3, 5, 7, 9, 12, and 15 hours after the injection of corticotrophin for the measurement of plasma 11-hydroxycorticosteroid concentration by the method of Mattingly (1962). Urine was collected in two six-hour periods after the corticotrophin injection for measurement of the urine 11-hydroxycorticosteroid concentration by the method of Mattingly *et al.* (1964).

Results

The plasma 11-hydroxycorticosteroid levels after the corticotrophin carboxymethylcellulose and gelatin preparations are given in Table I. Table II shows the urinary 11-hydroxycorticosteroid levels. The Chart shows the mean of the results obtained in the 10 subjects with the standard error of the mean.

A *t* test on means of the paired differences in plasma 11-hydroxycorticosteroid levels of all subjects at each time after the administration of corticotrophin showed that the gelatin preparation produced a greater rise of plasma 11-hydroxycorticosteroids than the carboxymethylcellulose preparation at 5, 7, 9, and 12 hours (5 hours $P<0.05$, 7 hours $P<0.05$, 9 hours $P<0.01$, 12 hours $P<0.02$). At 1, 3, and 15 hours the differences were not significant (1 hour $P<0.1$, 3 hours $P<0.1$, 15 hours $P<0.1$).

A *t* test performed on means of the paired differences in urinary 11-hydroxycorticosteroid excretion in 9 of the 10 subjects showed that there was not a significant difference in the urinary excretion of free 11-hydroxycorticosteroids during the first six hours after administration of the two types of corticotrophin ($P<0.1$). During the second six hours the gelatin preparation produced a greater excretion of 11-hydroxycorticosteroids than the carboxymethylcellulose preparation ($P<0.05$).



Means and standard error of means for each type of corticotrophin. The open circles represent the values obtained with carboxymethylcellulose and the closed circles the values with the gelatin preparation.

Discussion

Intramuscular injection of corticotrophin in saline produces a maximal adrenal-stimulating effect in two hours with a fall in plasma steroids to control levels in four to six hours (Bayliss and Steinbeck, 1954). The short duration of effect is due to enzymatic destruction of the corticotrophin at the site of injection or in the blood stream. The instability of the saline preparations has stimulated the search for long-acting preparations. The addition of a number of substances to corticotrophin has been shown to increase the duration of activity either by delaying the release of corticotrophin or by inhibiting enzymatic destruction of the corticotrophin at the site of injection. Aluminium phosphate in polyvinyl pyrrolidine (Wolfson *et al.*, 1951), procaine (Holbrook, 1951), cellulose and carboxymethylcellulose (Payne *et al.*, 1951; Nordström and Jensen, 1954), oils (Raben *et al.*, 1952), and gelatin (Raben *et al.*, 1952) have all been shown to enhance corticotrophin activity, probably by delaying release at the site of injection. The addition of zinc compounds to corticotrophin is thought to inhibit enzymatic destruction at the site of injection (Ferriman *et al.*, 1954; Homan *et al.*, 1954). The therapeutic efficiency of any individual preparation of corticotrophin is related to the con-

centration of corticotrophin and duration of activity, the latter being determined by the carrier vehicle.

A number of factors must be taken into account when comparing the corticotrophin preparations. Considerable variation in individual response to corticotrophin occurs (Bayliss and Steinbeck, 1954). In the present study this is shown by Subject 5 (Table I), who reacted differently from all the other subjects with respect to his response to the gelatin and carboxymethylcellulose preparation. The standardization of different preparations of corticotrophin may vary from batch to batch and from manufacturer to manufacturer. However, the carrier vehicle for corticotrophin is comparably much more important than minor variations in concentration. DiRaimondo and Forsham (1958) have shown that doubling the corticotrophin dose of a gelatin preparation prolongs the increase in steroidogenesis by approximately one hour. In the present study the gelatin preparation appears to be superior to the carboxymethylcellulose preparation at 5, 7, 9, and 12 hours. This difference suggests that gelatin is superior to carboxymethylcellulose in delaying release of corticotrophin from the site of injection and prolonging corticotrophin activity.

Hangård *et al.* (1960), investigating the effect of response of different types of repository corticotrophin preparations, including gelatin and carboxymethylcellulose, were unable to draw definite conclusions from their study. They suggest that individual variations in response and unequal potency of different preparations make comparative studies difficult. In their study they did not inhibit endogenous corticotrophin by pituitary suppression, which introduced a further variable. Hedner (1963) found that a corticotrophin-gelatin preparation had a significantly longer duration of action compared with a preparation of carboxymethylcellulose in equivalent dosage.

Because of its low viscosity, carboxymethylcellulose can be drawn up into a syringe and injected with ease. No prior warming of the preparation is required. This is an advantage. The gelatin preparation, however, has a high viscosity and requires warming before administration. Furthermore, the gelatin may solidify in the syringe, and if not injected soon after warming this may lead to some of the preparation being lost from the joint between the needle and the syringe if excessive force is used during the injection.

The present investigation and the published data available suggest that corticotrophin-carboxymethylcellulose does not have the same duration of activity as the gelatin preparation and is likely to be inferior therapeutically if used in equivalent dosage. Caution should be exercised when changing from one preparation to another in equivalent doses. At present carboxymethylcellulose does not seem to offer any therapeutic advantage over the gelatin preparation. The claim that carboxymethylcellulose "lasts like gel" is not substantiated.

Summary

A comparison has been made of the potency and duration of activity of two preparations of corticotrophin, one combined with gelatin and the other with carboxymethylcellulose. The plasma and urinary 11-hydroxycorticosteroid levels were measured in 10 normal subjects after an intramuscular injection of 40 international units of each preparation. The duration of activity of the carboxymethylcellulose preparation was less than that of the gelatin preparation in 9 out of the 10 subjects. Caution should be exercised when changing from one preparation to another in equivalent doses.

I am grateful to Crooks Laboratories Limited for supplies of carboxymethylcellulose preparation (Crooks A.C.T.H./c.m.c.) used in this study.

Cystic Adventitial Disease of the Popliteal Artery

G. J. T. LEWIS,* M.B., F.R.C.S.ED.; D. M. DOUGLAS,† M.B.E., CH.M., F.R.C.S., F.R.C.S.ED.
W. REID,‡ M.B., F.R.C.S.GLASG., F.R.C.S.ED.; J. KENNEDY WATT,§ CH.M., B.SC., F.R.C.S., F.R.C.S.GLASG.

Brit. med. J., 1967, **3**, 411–415

In 1954 Ejrup and Hiertonn recorded a case of stenosis of the popliteal artery caused by a cyst arising from the adventitia, and this case and three similar ones were described by Hiertonn, Lindberg, and Rob (1957) as "cystic degeneration of the popliteal artery." The cardinal features they described were those of a localized arterial disease of young adult males causing intermittent claudication of sudden onset, which was successfully treated by resection of the affected arterial segment with autogenous vein graft or arterial homograft replacement.

This condtion is rare, and of the 32 cases described in the literature 24 have involved the popliteal artery (Sutton, 1962; Hamming and Vink, 1965; and others). It has also been described in the external iliac artery (Atkins and Key, 1946; Jacquet and Meyer-Burgdorff, 1960), the radial artery (Parkes, 1961; Bäckström, Linell, and Ostberg, 1965), and the ulnar artery (Parkes, 1961), and Hiertonn (1966) mentions a case in which the lesion arose from a small branch of the popliteal artery.

This paper presents three additional cases affecting the popliteal artery and reviews the literature on the condition.

Case 1

A boy aged 13 presented at the peripheral vascular unit, Glasgow Royal Infirmary, in March 1964. The previous month, during a gym period at school, he felt a sudden cramping pain in the left calf, and subsequently experienced pain in the left calf and popliteal fossa which stopped him walking at 100 yards (90 metres), and which was relieved by rest. He also complained that the left foot was colder than normal and often became white.

On examination there was wasting of the left calf. The left common femoral pulse was normal, but the left popliteal, posterior tibial, and dorsalis pedis pulses were absent and there was pallor of the left foot on elevation. Oscillometry showed an absence of pulsation in the left calf but normal pulsation in the left thigh. The right leg was normal. A femoral arteriogram showed a smooth stenosis of the popliteal artery, 2 cm. long, at the level of the femoral epiphysial line. The sural arteries arose from the stenosed area and the remaining vessels were normal.

In June the left popliteal artery was explored and found to be dilated immediately above the level of the knee joint, and though dissection caused marked proximal spasm the artery was otherwise normal. On incising the adventitia of the "dilatation," gelatinous material extruded from between the adventitia and media. The media and intima were normal and the arteriotomy was repaired with a vein patch. At the completion of operation normal pulses had returned to the leg.

In August 1966, 27 months postoperatively, he was symptom-free and there was no clinical abnormality of the leg.

Case 2

A man aged 42 presented at the peripheral vascular unit, Glasgow Royal Infirmary, in April 1964 with an 18-month history of claudication in the left calf, discomfort behind the left knee, and numbness of the left foot on walking half a mile (800 metres). There was no other relevant history.

On examination the femoral, popliteal, and posterior tibial pulses were normal but the dorsalis pedis pulse was absent. In the left popliteal fossa there was a visible swelling which was poorly defined, non-pulsatile, and of rubbery consistency. He was admitted for arteriography in July, by which time his claudication was forcing him to stop at a quarter of a mile (400 metres) and the left popliteal and posterior tibial pulses were diminished. A left femoral arteriogram on two occasions failed to demonstrate the superficial femoral artery but a right femoral arteriogram was normal. Left phenol lumbar sympathectomy was performed and his claudication distance increased to more than one mile (1,600 metres) at a normal pace.

The popliteal cyst was thought to be a semimembranosus bursa, but at exploration in October it was found to arise from the anterior wall of the popliteal artery and there was no communication with the knee joint. On incising the cyst a quantity of thick "jelly" extruded. The cyst wall was partially excised, after which the popliteal artery pulsated normally. Postoperatively the popliteal and posterior tibial pulses were normal, and he was asymptomatic for about one year.

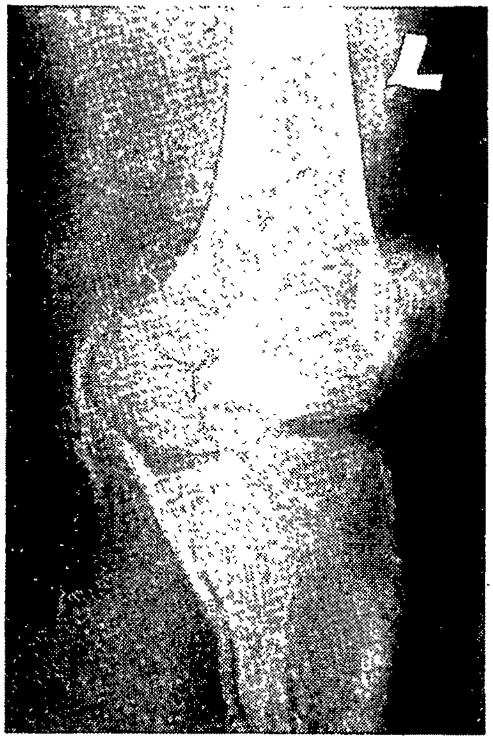

FIG. 1.—Case 2. Arteriogram showing posterior displacement of the popliteal artery due to the cyst.

He then had recurrence of claudication at 400 yards (365 metres), and on examination it was found that the popliteal cyst had recurred and was pushing the popliteal artery posteriorly so that the popliteal pulse was more easily palpable than normal and there was an audible bruit. Arteriography showed postero-medial displacement of the artery (Fig. 1). Ten millilitres of viscous homogeneous gel with a pinkish hue was aspirated from the cyst and he again became asymptomatic.

§ Peripheral Vascular Unit, Glasgow Royal Infirmary and Belvidere Hospital, Glasgow.

When readmitted in August 1966 he was symptom-free, but a systolic bruit was audible over the easily palpable popliteal artery. At exploration the cyst lay anterior to the popliteal vessels at the level of the knee joint, being bound to the artery and vein by a tough outer sheath of fibrous tissue, which when divided revealed a translucent thin-walled mutilocular cyst. A plane of cleavage existed between the artery and cyst at all but one point where a stalk was present about 2 mm. in diameter and length (Fig. 2), and here the cyst had to be cut off the artery. Histology of the specimen showed several cysts with fibrous connective-tissue walls which peripherally incorporated a very small amount of elastic fibres and with a lining of flattened fibroblast-like cells. Gradations from fully formed cysts to regions of myxomatous degeneration were present (Fig. 3). There was no evidence of neoplasm or inflammation.

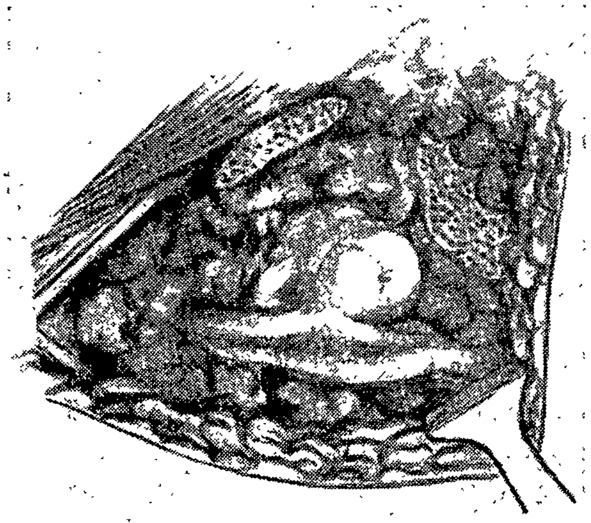

FIG. 2.—Case 2. Findings at operation. The medial head of gastrocnemius has been divided. The lobulated cyst arises from the anterior wall of the artery and the vein is crossing the artery at this level.

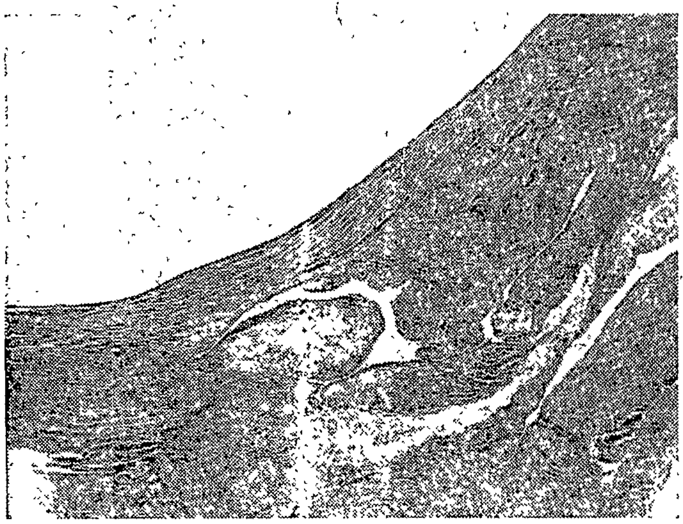

FIG. 3.—Case 2. Photomicrograph of cyst showing the connective-tissue wall and gradations from regions of myxomatous degeneration to fully formed cysts. (Haematoxylin and eosin. ×33.)

Case 3

A man aged 55 attended the vascular clinic at Dundee Royal Infirmary on 20 July 1964 complaining of pain in the right calf on walking 100 yards (90 metres). The onset was gradual over a period of two to three months.

Examination of the right leg showed that all peripheral pulses beyond the femoral artery were absent whereas the pulses in the left leg were normal. Arteriography showed a stenosis of the popliteal artery, and a provisional diagnosis of early atheromatous change was made (Fig. 4).

On 24 July the popliteal artery was explored and a curious cystic mass of tissue involving the adventitia was disclosed. It measured 3 cm. in length and 2 cm. in width, and when it was dissected clear of the vessel the latter took on a normal appearance.

Postoperatively pulsation returned to his pedal vessels, his claudication disappeared, and arteriography showed a return of the vessel to a normal appearance (Fig. 4).

He returned to the vascular clinic on 26 April 1965, 10 months after operation, with a complaint of pain on walking. Arteriography on 9 July showed slight narrowing and irregularity of the proximal part of the popliteal artery. However, his distal pulses were normal, and when seen again on 17 September he was symptom-free.

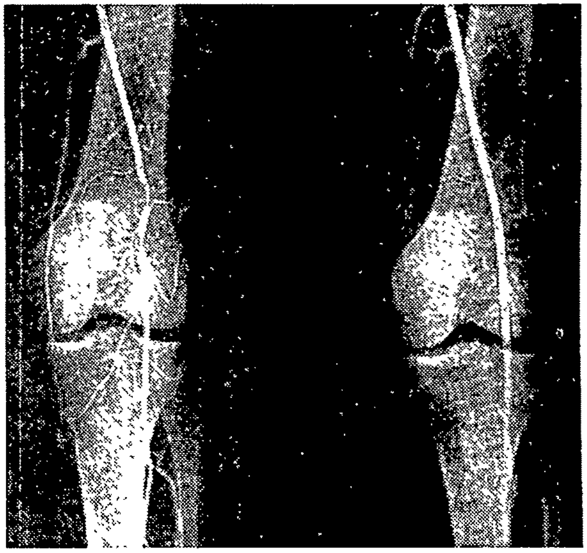

FIG. 4.—Case 3. Preoperative and postoperative arteriograms. In the preoperative picture there is striking demonstration of the development of the geniculate anastomosis around the knee joint. Postoperatively the arteriographic appearance is normal.

The histology of the lesion (Fig. 5) was reported as: "The specimen was a ragged piece of tissue, 12 by 8 by 6 mm., of firm consistency and yellowish-white cut surface. Sections show it to consist of varying cellular fibrous tissue in which there are many fairly sharply circumscribed areas of mucinous degeneration. Various stages in the process leading up to the end-stage of formation of "lakes" of metachromatic mucin can be seen. There would appear to be an initial overgrowth of the fibroblasts, then their gradual conversion to swollen cells with finely granular or foamy cytoplasm; and finally a bursting of the cells with release of the now mucinous contents. The process is akin to that which produces the 'ganglion' in association with the tendon or tendon sheath, but it appears, clinically, that the association was wholly

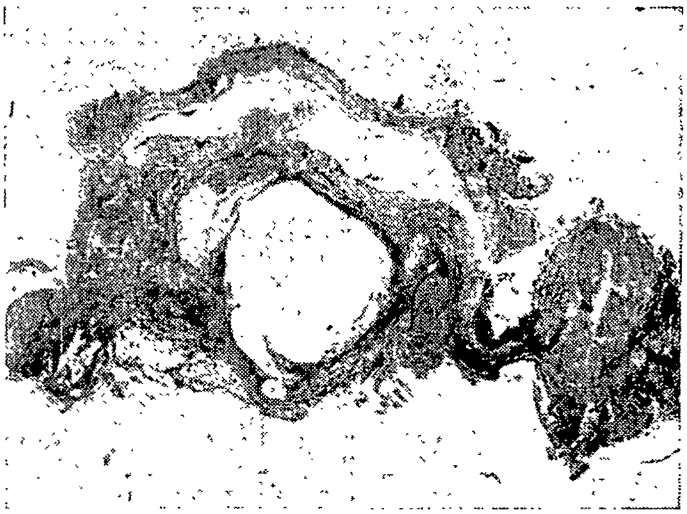

FIG. 5.—The whole section of the lesion removed at operation, showing the cystic spaces which were filled with gelatinous material.

with the wall of the popliteal artery. It is thus difficult to go further than to classify this as ' myxoma of arterial adventitia.' "

Discussion

Cystic degeneration of the political artery is a rare condition the cause of which is unknown. The incidence in the peripheral vascular unit, Glasgow Royal Infirmary, is approximately 1 in 1,200 of those patients presenting with claudication or 1 in 1,000 of those undergoing arteriography, an incidence similar to that reported by Hamming and Vink (1965). The sex incidence in the literature is eight males to one female, which approximates to the sex incidence of occlusion in the lower limb due to atherosclerosis. The three cases reported in females have all involved the popliteal artery. The average age of affected males is 36 years and of females 49 years.

The aetiology of the lesion is obscure. It seems unreasonable to ascribe its development to degenerative changes in an atherosclerotic or otherwise abnormal arterial wall, as our first patient (Case 1) was 13 years of age and Harris and Jepson (1965) described its occurrence in a boy of 11 years, and for this reason the title " cystic degeneration " appears to be a misnomer. Histology shows no evidence of haemorrhage, inflammation, or neoplasia, and the appearance is similar to that found in ganglia elsewhere. On the other hand, ganglia are most commonly found in the late teens and twenties (McEvedy, 1962), whereas this condition has its greatest incidence in the late thirties, a time when atherosclerosis is often developing.

The media and intima are usually intact and any damage to them is probably secondary (Hiertonn *et al.*, 1957 ; Andersson, Gothman, and Lindberg, 1959). Harris and Jepson (1965) reported a significant amount of hydroxyproline present in the

Nature of Lesion and Results of Treatment in 24 Cases of Cystic Adventitial Disease of the Popliteal Artery

Case No.	Year Reported	Author	Age	Sex	Onset	Arteriogram	Year	Operation Findings	Operation	Histology	Condition at Follow-up

Note: Cases reported by Hamming and Vink (1965), Grepe (1963), Sutton (1962), and Bartos (1966) are not reviewed above.

gel and suggested that this indicated its origin from collagen tissue, but quantitative analysis of the protein of the gel from Case 2 does not support this view (see Addendum). Most authors—for example, Ishikawa, Mishima, and Kobayashi (1961)—have suggested that repeated minor trauma to the popliteal artery plays a significant part. The fact that the lesion is almost always in close association with the back of the knee joint and that gelatinous degeneration of the tendon sheaths in this region is common raises the possibility that regional factors may be concerned—for example, the range of movement of the knee joint and of the adjacent artery and tendons. But a more attractive theory might be the incorporation, during development, of mucin-secreting cells from the endothelium of the knee joint in the adventitia of the artery. These cells secreting small amounts of mucin over many years might eventually give rise to tense adventitial cysts which encroach on the lumen of the vessel.

The usual presenting symptom is intermittent claudication, which may be of gradual or sudden onset and may be accompanied by a cold white foot and pain. Sometimes the initial symptoms are episodic and the pain is atypical of claudication (Barnet and Morris, 1964 ; Hiertonn *et al.*, 1957). The pulse pattern is variable, and in the two cases with "ischaemic rest pain" the lower-limb pulses were normal (Chevrier, 1962 ; Mentha, 1965), suggesting a neuritis from pressure on the popliteal nerves. Exercise or knee flexion may cause the disappearance of distal pulses (Ishikawa *et al.*, 1961). A visible and palpable swelling (Case 2) has not previously been reported, though Lambley (1963) noted the affected popliteal artery to be more easily palpable than normal and Mentha (1965) recorded a bruit at the level of the stenosis.

The condition can usually be recognized by the typical arteriographic appearances, which show a localized lesion at or above the level of the knee joint in an otherwise normal popliteal artery. The lesion may cause stenosis, occlusion, or displacement of the artery. The stenosis is a smooth indentation of the arterial wall which may be one-sided or hour-glass in appearance, and which may vary in severity with the pulse wave (Jacquet and Meyer-Burgdorff, 1960) or posture (Bliss, Rhodes, and Rains, 1963). Similar stenotic appearances may be caused by a local atheromatous plaque, but post-stenotic dilatation has not been noted with cystic degeneration and in doubtful cases a lateral arteriogram may show irregularity. With adventitial cysts, lateral views may also show posterior displacement of the artery (Case 2) or a rigid arterial segment causing kinking of the artery when the knee is flexed (Ishikawa *et al.*, 1961). Occlusion may be due to contact between the intimal surfaces of the artery (Hiertonn *et al.*, 1957 ; Harris and Jepson, 1965), but more often it is due to thrombosis after severe stenosis. Once thrombosis has occurred, the arteriographic appearances resemble those of arteriosclerosis, though a smooth tapering-off at the limits of the occlusion (Andersson *et al.*, 1959)—aply termed the "scimitar" effect by Harris and Jepson (1965)—may suggest cystic pressure.

At operation the lesion most commonly appears as a well-defined lump, bluish in colour, non-pulsatile, elastic in consistency, and of variable length (2–9 cm.), and it may lie to one side of, or partially or completely invest, the artery. It has also been described as a dilatation of the artery (Simon, 1963) as yellowish brown in colour (Ishikawa *et al.*, 1961) and as a pulsatile lump (Lambley, 1963 ; Tytgat, Derom, and Galinsky, 1958). Dense periarterial adhesions similar to those found in Case 2 have been reported by other authors (Hiertonn *et al.*, 1957 ; Robb, 1960 ; Tytgat *et al.*, 1958 ; Ishikawa *et al.*, 1961 ; Bliss *et al.*, 1963).

The type and outcome of surgical treatment in 24 cases are summarized in the Table ; all the cases appear to have had excellent initial results. The late results in 13 of them have been obtained by correspondence with previous authors. When a stenosis is present, incision of the cyst with extrusion of the gel or excision of the cyst in toto (with or without arteriotomy) may give a satisfactory long-term result, but when occlusion is present arterial resection with autogenous vein graft should be performed, as synthetic grafts at this level are prone to occlusion. Case 2 supports the view that recurrence may follow partial excision of the cyst (Bäckström *et al.*, 1965), and Rains (1966) writes of the recurrence of claudication four years after incision alone. In contrast, in one case the arteriogram returned to normal after lumbar ganglionectomy and cyst aspiration and the patient was symptom-free six years later (Mentha, 1966).

Summary

Cystic adventitial disease of the arteries is a rare and only recently recognized entity which most commonly occurs in the popliteal artery, causing intermittent claudication. Three further cases affecting the popliteal artery are presented.

The aetiology of the condition is obscure. The cyst containing gel may be unilocular or multilocular, and appears to arise from the arterial adventitia. Histology shows no evidence of haemorrhage, inflammation, or neoplasia. The absence of hydroxyproline in the gel is against an origin from collagen or elastin, and its occurrence in children is against degenerative changes in the arterial wall.

The typical clinical picture is of intermittent claudication of sudden onset in a young adult male. The pulse pattern is variable and the popliteal pulse may be absent or more easily palpable than normal, or an audible bruit may be present over it. Exercise or knee flexion may cause the disappearance of pedal pulses.

The arteriographic appearance is of stenosis, displacement, or occlusion at or above the level of the knee joint in an otherwise normal popliteal artery.

A review of the results of treatment indicates that after complete excision of the cyst (with or without arteriotomy) or arterial resection with autogenous vein-graft replacement the prognosis is excellent.

We wish to thank Mrs. J. Lewis for the operative illustration in Case 2 ; Dr. D. Raeside and Dr. George Howie for the excellent arteriograms ; Dr. E. Walker and Dr. W. W. Park for the histological studies ; and Mr. P. Kelly for some of the photographic reproductions. Finally, we thank all those previous authors who so kindly provided us with their long-term follow-up findings.

Addendum: Amino-acid Analysis of Protein Present in a Popliteal Artery Cyst

G. LEAF,* M.SC., PH.D.

The gel obtained from the cyst in Case 2 was stored frozen at −20° C. A portion was analysed by the microKjeldahl method and found to contain 0.52% nitrogen, corresponding to a protein content of approximately 3%. The remainder of the gel was lyophilized and 3 mg. of the dried material was hydrolysed with 1 ml. 6N HCl in an evacuated sealed tube at 115° C. for 20 hours. Hydrochloric acid was removed from the hydrolysate in a rotary evaporator and the residue analysed for amino-acids by Piez and Morris's (1960) modification of the method of Spackman, Stein, and Moore (1958). The results are shown in the Table, where they are compared with values for collagen from human tendon (Eastoe, 1955) and elastin from bovine aorta (Gotte, Stern, Elsden, and Partridge, 1963). The absence of hydroxyproline and hydroxylysine from the hydrolysate was confirmed by paper chromatography with the use of butanol/acetic acid/water (4:1:5) and water-saturated phenol as solvents and both ninhydrin and isatin as staining reagents. The paper chromatograms confirmed the presence of substantial amounts of glucosamine.

It will be noted that the amino-acid composition of the protein differs markedly from that of a representative collagen, and the failure to detect hydroxyproline suggests that neither collagen nor elastin could be present in more than traces. The presence of glucosamine and the fact that the amino-acids recovered account for only 53.6% of the dry matter suggest that the main constituent may be a mucoprotein. There was insufficient material to investigate this matter further.

Amino-acid Composition of Protein from Popliteal Cyst Compared with Those of Collagen and Elastin

	Cyst Protein	Collagen	Elastin
Aspartic acid	38·4	50·5	15·6
Threonine	24·4	19·3	13·4
Serine	23·2	38·5	10·5
Glutamic acid	52·9	75·5	23·1
Proline	23·6	127·2	117·3
Hydroxyproline	0	96·2	11·4
Glycine	87·0	338·0	318·7
Alanine	41·0	115·6	223·6
Cystine	19·0	0	0
Valine	29·0	26·5	136·7
Methionine	4·3	6·0	2·0
Isoleucine..	6·4	9·5	30·5
Leucine	32·3	27·2	67·2
Tyrosine	11·2	3·8	12·7
Phenylalanine	18·8	14·8	36·4
Lysine	42·3	22·5	8·2
Histidine	9·5	5·6	1·9
Arginine	19·9	51·2	9·8
Glucosamine	29·2	—	—
Hydroxylysine	0	9·3	—

Values are expressed as μmoles amino-acid per 10^5 g. dry matter for the unknown protein and μmoles per 10^5 g. protein for collagen (human tendon, Eastoe, 1955) and elastin (bovine aorta, Gotte *et al.*, 1963).

Medical Memoranda

Chronic Thyrotoxic Myopathy with Involvement of Respiratory and Bulbar Muscles

Brit. med. J., 1967, **3**, 415–416

Numerous reports of chronic thyrotoxic myopathy have followed Bathurst's (1895) original description. The incidence of respiratory and bulbar muscle weakness in previously reported cases was extremely rare; furthermore, in most of these cases the diagnosis could be challenged because of lack of proper documentation or correct interpretation. In a review of the condition by Whitfield and Hudson (1961) the respiratory and bulbar muscles were not mentioned, and in a reappraisal by Havard (1962) it was stated that these muscles are little if at all affected.

This report describes a case of chronic thyrotoxic myopathy in which weakness of the respiratory and pharyngeal muscles was a prominent feature.

CASE REPORT

An 83-year-old man was admitted to hospital with nine months' history of progressive loss of weight, generalized weakness and lassitude, shortness of breath on exertion, and difficulty in swallowing. During that period he was investigated elsewhere but no definite diagnosis was made. Initially he was described as being thin, but he looked fit and active and no abnormal physical signs were noted. Three months before admission he developed oedema of the ankles and distension of the neck veins; he was treated for congestive cardiac failure but his condition continued to deteriorate.

When first seen in hospital he had lost 3 stones (19 kg.) in weight. He was dyspnoeic at rest and so weak that he had difficulty in rising from the sitting or lying position; he was unable to swallow solid food and had difficulty with liquids.

On examination he looked emaciated and ill. The pulse was regular at 90 a minute, was collapsing in character, and the blood pressure was 160/60. The apex beat was forcible but not displaced. The jugular venous pressure was raised and he had oedema of the ankles. Chest expansion was poor and there were a few scattered rhonchi in both lung fields. The liver and spleen were not palpable. The striking findings were confined to the neuromuscular system, which showed profound weakness and wasting of the proximal and distal muscles of the limbs and of the trunk muscles. There were no fasciculations and the tendon reflexes were normal. The cranial nerves were intact and there was no sensory loss.

The thyroid gland was not enlarged and no thyroid bruit could be heard. There were no eye signs, apart from a slight lid lag. His hands were warm and he had fine tremors of the outstretched fingers.

Investigations.—Hb 14 g./100 ml.; white cell count 5,000/cu. mm.; E.S.R. 22 mm. in one hour (Westergren); blood urea 47 mg./100 ml. Serum electrolytes, liver-function tests, and glucose-tolerance curve were normal. Chest *x*-ray examination showed a normal-sized heart and clear lung fields, and the E.C.G. was normal. Barium studies of the gastrointestinal tract did not reveal any abnormality.

In view of the negative barium studies, the dysphagia was ascribed to weakness of the pharyngeal muscles as part of a generalized myopathy. The diagnosis of chronic thyrotoxic myopathy was confirmed by thyroid function studies which showed protein-bound iodine 12.7 µg./100 ml., radioactive iodine uptake 87.7% at four hours and 70% at 24 hours, and B.M.R. +21% and +24%. Myasthenia gravis was excluded by a negative edrophonium chloride (Tensilon) test.

Respiratory Function Tests

	Before Treatment	After Isoprenaline Inhalation	After Intravenous Edrophonium (10 mg.)	15 Days	3 Months
				After Treatment	
Vital capacity (ml.)	1,550	1,500	1,600	2,500	3,000
Predicted V.C. (ml.)	3,000	3,000	3,000	3,000	3,000
% of predicted V.C.	52	50	53	83	100
% in 0·75 second ..	40	41	43	42	45
M.B.C. (l./min.) ..	25	25	27	42	54
Predicted M.B.C. ..	70	70	70	70	70
% of predicted M.B.C.	36	36	39	60	77
Peak expiratory flow rate (l./min.) ..	185	220	190		270
Arterial blood:					
*p*H	7·404				
CO_2 tension ..	42·5 mm. Hg				
O_2 saturation ..	95·5%				
Po_2	84 mm. Hg				

The respiratory function tests (see Table) showed a moderate degree of airway obstruction with an F.E.V.$_{0.75}$ of 40% but a considerable reduction in vital capacity to 52% of the predicted value, presumably due to respiratory muscle weakness. There was no improvement in the vital capacity after isoprenaline inhalation or intravenous edrophonium.

The patient was treated with carbimazole 20 mg. t.d.s. at first, but the dose had to be increased subsequently to 30 mg. t.d.s. Improvement began on the seventh day, and when he was seen three months later his symptoms had completely subsided. The dysphagia was one of the first symptoms to respond, and after two weeks' treatment swallowing had returned to normal. The response of respiratory function was dramatic, and on the fifteenth day of treatment the vital capacity was 83% of the predicted value.

It is interesting to note that as soon as clinical improvement became manifest the patient developed overt signs of hyperthyroidism with motor hyperactivity and a marked lid retraction and lid lag. These signs were presumably masked by the severe muscle weakness.

DISCUSSION

In many respects the clinical features of this case resemble those in previous reports. Thus the relatively short duration of the illness, the masking of signs of thyrotoxicosis, the distribution of muscle weakness and wasting, and the excellent response to treatment have all been emphasized in the past. In addition, the severity of thyrotoxicosis as shown by thyroid-function tests has been stressed.

The B.M.R. is usually high but, as in the present case, it may be only slightly raised (Millikan and Haines, 1953 ; Collings and Lienhard, 1957 ; Gimlette, 1959).

Electromyographic and histological techniques have been extensively studied and frequently reported in the past but have failed to provide any help in the diagnosis ; the findings have been normal, equivocal, or non-specific (Millikan and Haines, 1953 ; Kite *et al.*, 1954 ; Collings and Lienhard, 1957 ; Hed *et al.*, 1958 ; Melville, 1959). It has also been shown that there is no quantitative difference in creatinine excretion in patients with chronic thyrotoxic myopathy or uncomplicated thyrotoxicosis (Quinn and Worcester, 1951). These tests were not carried out in our patient. It is now generally agreed that the diagnosis should mainly depend on clinical assessment, and an essential requirement is a satisfactory response to treatment.

Weakness of the respiratory and bulbar muscles has been described in cases of "acute thyrotoxic myopathy"; it is doubtful, however, if this condition exists as a distinct entity, and it would appear that such cases were probably examples of myasthenia gravis associated with thyrotoxicosis (Millikan and Haines, 1953).

In chronic thyrotoxic myopathy involvement of these muscles must be exceedingly rare or overlooked in its milder forms. In five previously reported cases there were insufficient data to reliably exclude myasthenia gravis.

Death from respiratory failure has been reported in three cases ; the case reported by McEachern and Ross (1942) was thought to be an example of chronic thyrotoxic myopathy in spite of a myasthenic defect in the electromyogram and a positive response to neostigmine. In the other two cases myasthenia was not excluded (Morgan and Williams, 1940 ; Thorn and Eder, 1946).

Dysphagia was the presenting symptom in the case reported by Leach (1962), but the patient was also suffering from dystrophia myotonica.

Heinrich *et al.* (1962) reported a case of "encephalopathic hyperthyroidism" in a man aged 70 who presented with dysphagia, had most of the features of chronic thyrotoxic myopathy, but, in addition, had a few neurological signs which could well have been due to an associated cerebrovascular disease.

I am grateful to Dr. C. E. Davies for allowing me to report this case.

Current Practice

GROWING POINTS

Autoimmune Disease—I

G. L. ASHERSON,* D.M., M.R.C.P.

In some human diseases antibodies react with human tissue *in vitro*. These antibodies are called *autoantibodies*, and are found in rheumatic fever, Hashimoto's thyroiditis, systemic lupus erythematosus, and other diseases. The presence of autoantibodies is compatible with the view that tissues are damaged by an autoimmune process directed against components of the patient's own tissues. For this reason Hashimoto's thyroiditis and systemic lupus erythematosus are called *putative* autoimmune diseases.

For readers wishing to learn more about autoimmunity the recent books by Humphrey and White (1964) and Glynn and Holborow (1965) are recommended. The bibliography for the statements made in this article is given by Asherson (1965).

Tissue Damage due to Immune Reactions

The tissue damage caused by autoimmune reactions to the components of an animal's own tissue is a special example of tissue damage due to immune reactions. There are two main types of immunological tissue damage: that due to humoral factors (antibodies) and that due to cellular factors. The former is called *immediate hypersensitivity* ; the lesions characteristically appear within minutes or hours of exposure to antigen, and histological examination shows exudation of plasma and infiltration with polymorphs in some cases. The latter is called *delayed hypersensitivity* ; the lesions reach a maximum 24 to 48 hours after exposure to antigen, and histology shows infiltration with chronic inflammatory cells such as histiocytes and lymphocytes.

Immediate hypersensitivity reactions can be transferred passively from one person to another with serum (passive transfer). In the Prausnitz-Kustner reaction intradermal injection of serum from an allergic person causes local weal and flare when antigen is injected into the same area. In contrast the delayed hypersensitivity reaction—for example, the tuberculin reaction—cannot be transferred by serum alone, and cells such as peripheral white cells, or lymph-node, spleen or peritoneal exudate cells are required for its passive transfer from one animal to another.

Immediate Hypersensitivity

Patients injected with penicillin sometimes produce antibodies against the drug, so that when they meet penicillin again anaphylactic shock or urticaria develops. Other antibodies cause vascular damage with polymorph infiltration of arteriolar walls, where they react with their corresponding antigen. This is known as the *Arthus reaction*, and may be important in the pathogenesis of certain types of arteritis.

Antibodies may also be directed against components of the animal's own tissue. Patients with Hashimoto's thyroiditis have a cytotoxic antibody which, in the presence of complement, kills thyroid cells in tissue culture. Yet other antibodies are unable to cause tissue damage, either because they have the wrong biological properties or because they are directed against an inappropriate or inaccessible antigen. Many apparently healthy people have autoantibodies against thyroglobulin which are not thought to cause tissue damage. Babies of mothers with systemic lupus erythematosus have circulating antibodies against nuclei (*antinuclear factor*) which has crossed the placenta: these do not cause tissue damage and cannot penetrate the nuclei of intact cells. (See Fig. 1.)

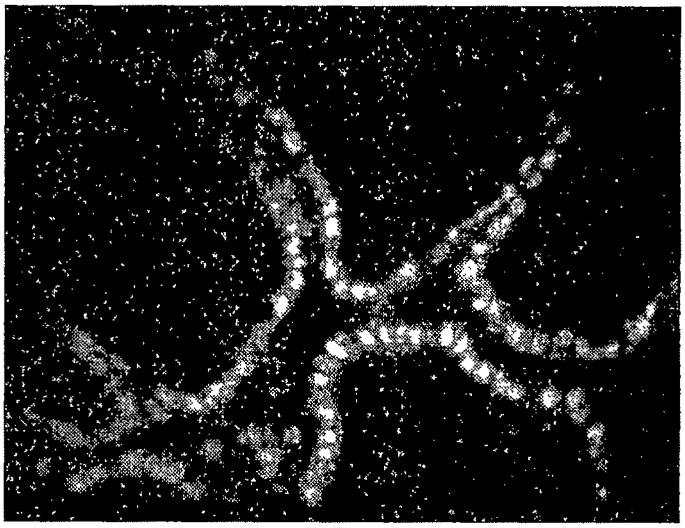

FIG. 1.—Antinuclear factor demonstrated in the serum of a patient with systemic lupus erythematosus by immunofluorescence using calf thyroid (by courtesy of Dr. E. J. Holborow).

At the other extreme certain antibodies are protective. After they have recovered from experimental allergic (autoimmune) encephalomyelitis rats have an antibody which protects other rats from the encephalomyelitis which would otherwise follow injection of brain in Freund's adjuvant. The antibody acts by blocking the induction or the damaging effect of immune responses, and this protective effect is called *immune enhancement*.

Complement

Complement is the name given to a group of factors in normal serum which are necessary for the haemolytic, cytotoxic, and certain other damaging actions of antibody. Thus red cells are agglutinated *in vitro* by certain physicochemical types of antibody, but they are lysed only in the presence of complement. Indeed, red cells coated with antibody (sensitized red cells) are used to detect complement.

---

* Reader in Immunology, Department of Bacteriology, the London Hospital Medical College, London E.1.

At suitable concentrations many antibodies will form precipitates with soluble antigens. When the concentration of antigen is high, however, these complexes are soluble, and soluble antigen–antibody complexes are thus formed. These complexes often fix—that is, combine with—the components of complement, and so cause glomerular and vascular damage. They may be responsible for renal damage in systemic lupus erythematosus.

In the presence of complement antigen–antibody complexes release a soluble factor which promotes the migration of polymorphs. This may be important in causing the polymorph infiltrate in the Arthus reaction and the damaging effect of soluble antigen–antibody complexes.

Delayed Hypersensitivity

The Mantoux reaction is the classical example of delayed hypersensitivity. The site of injection of tuberculin becomes infiltrated with lymphocytes and histiocytes, and the maximal reaction occurs after 24 to 48 hours. In animals this lesion can be transferred by cells but not by serum alone. This indicates that delayed hypersensitivity is not due to a conventional circulating antibody. It is sometimes explained by postulating a hypothetical antibody which is bound to the cells.

Despite the development of certain *in-vitro* tests in man delayed hypersensitivity has only been detected by skin tests.

In autoimmune disease it is customary to attribute tissue damage to delayed hypersensitivity, partly because of its importance in experimental autoimmune disease, and partly because there is a poor correlation between the presence of circulating antibody and tissue damage in diseases such as Hashimoto's thyroiditis. Though serum alone will not transfer delayed hypersensitivity in animals, cells and serum are synergic in transferring delayed hypersensitivity to several protein antigens. The implication is that in autoimmune disease tissue damage may be due to both cellular and humoral factors rather than to either singly.

Mode of Production of Autoimmune Responses

Autoimmune responses are a special example of immune responses. They are those responses in which the antibody will combine with the animal's own tissue components *in vitro,* or in which delayed hypersensitivity can be produced with the animal's own tissue components. Tissue damage is not a constant feature of the autoimmune response, either because the type of response is inappropriate or because the antigen is inaccessible. By definition it is not necessary that the production of an autoantibody should be stimulated by the animal's own tissue components. Indeed, tissue from other species (*heterologous* tissue) is usually better than tissue from the same species (*homologous* tissue) in causing the production of autoantibodies. Autoimmune responses should be distinguished from *isoimmune* responses[1] —for example, the blood-group antibodies, which react with the red cells of some but not all humans and which do not react with the subject's own red cells.

Immune Tolerance

The first exposure to an antigen may alter the effect of the second exposure to it in several different ways. The classical effect of the first injection of antigen is to increase the magnitude and speed of the response to the second injection: this is known as the *secondary response.* When soluble antigen is given in neonatal life, however, the response to the second injection is depressed. For instance, the injection of bovine serum albumin into newborn rabbits prevents the production of antibody which otherwise follows the injection of bovine serum-albumin in later life: this is known as *immune tolerance.* Some antigens are also able to suppress immune responses in adult animals in long-continued low dosage or very high single doses, while intermediate doses favour antibody production: this is known as *immune paralysis,* and it is thought to be the same type of phenomenon as immune tolerance.

The conditions for suppressing delayed hypersensitivity are less exacting than the conditions for suppressing the production of antibody. This selective diminution of delayed hypersensitivity is called *immune deviation,* and it may be important in limiting tissue damage even when autoantibodies are formed.

Normally animals do not produce antibodies against their own tissue components because of immune tolerance, though there are three situations in which autoantibodies are characteristically produced.

Antigens Similar to but not Identical with Self

When animals are injected with tissue similar to but not identical with their own tissue components autoantibodies are formed and sometimes tissue damage occurs. This is a general and important mechanism. Weigle showed that rabbits injected with rabbit thyroglobulin failed to produce autoantibodies or tissue damage. On the other hand, injection of chemically *altered* thyroglobulin (without adjuvant) led to the formation of autoantibodies against rabbit thyroglobulin and to the production of thyroiditis. This provides direct evidence that *altered* self components can cause tissue damage. Another possible example is the formation of autoantibody which occurs in rats whose livers are damaged by the injection of carbon tetrachloride.

Certain bacteria have antigens similar to those in mammalian tissue. The group A beta-haemolytic streptococcus has antigens similar to human heart, and the nephritogenic type 12-streptococcus has antigens similar to human kidney. *Escherichia coli* has antigen similar to human colon. These bacteria will cause antoantibody formation against heart and colon in animals, and it is thought that the antibodies against heart and colon found in rheumatic fever and ulcerative colitis may arise through this mechanism.

Immunization with Adjuvant–Antigen Mixtures

Certain materials (*adjuvants*) increase the intensity and change the nature of the immune response. The best-known example is Freund's complete adjuvant, which consists of a creamy emulsion of an aqueous solution of antigen, paraffin oil, and detergent, to which dead tubercle bacilli are added. Freund's *complete* adjuvant—i.e., with tubercle bacilli—has four distinctive actions, which do not occur when Freund's *incomplete* adjuvant—i.e., without tubercle bacilli—is used. These are:

(1) Increased delayed hypersensitivity.

(2) Increased production of cytotoxic antibody.

(3) Increased production of antibody which adheres to macrophages (cytophilic antibody).

(4) Increased production of autoimmune disease and autoantibodies when antigens such as brain, testis, peripheral nerve, thyroid, adrenal, kidney, labyrinth, uvea, and muscle are injected.

The role of Freund's complete adjuvant in producing experimental autoimmune disease has been used as evidence that delayed hypersensitivity is important in the pathogenesis of autoimmune disease. It is not clear whether Freund's complete adjuvant favours autoantibody formation by altering the immune system, or whether it also causes the antigen to be altered so that it becomes similar but not identical with self.

---

[1] The nomenclature used in transplantation work is different. Antigens identical with those of an animal are called *isologous*, while those differing are called *homologous*. The new terms *syngeneic* and *allogeneic*, respectively, avoid this confusion.

Familial Factors

New Zealand black mice (NZ/B mice) spontaneously develop haemolytic anaemia and glomerulonephritis associated with antibodies against red cells and antinuclear antibodies. Germinal centres which appear in the thymus resemble those seen in systemic lupus erythematosus and myasthenia gravis. The disease provides a useful model of systemic lupus erythematosus. Recent evidence shows that these mice carry a leukaemia virus which may be important in their disease.

Classification of Human Autoimmune Disease

Three major groups of autoimmune disease may correspond to the three groups which can be produced in animals:

(1) Diseases in which micro-organisms cause an autoimmune process. Possible examples are rheumatic fever, acute glomerulonephritis, and primary atypical pneumonia.

(1*a*) Diseases (or autoantibody production) due to exposure to altered or secluded tissue components. Examples are the production of antibody to heart, spermatozoa, and pancreas after damage to the corresponding organ.

(2) Hashimoto's thyroiditis and diseases such as pernicious anaemia and Addison's disease (non-tuberculous adrenalitis), which show clinical, serological, and familial overlap with it. The autoantibodies found characteristically react with *organ-specific* antigens in the thyroid, stomach, and adrenal. Autoantibodies reacting with widely distributed antigens (*non-organ-specific* autoantibodies) are rarely found.

(3) Systemic lupus erythematosus and other diseases, apparently affecting many systems, which sometimes merge clinically with systemic lupus erythematosus. These diseases usually show a high incidence of antinuclear factor and other autoantibodies against widely distributed antigen. Organ-specific antigens of the type seen in the Hashimoto group of diseases have a normal or only slightly raised incidence.

Detection of Autoantibodies

The finding of autoantibodies is important in the diagnosis of putative autoimmune diseases. There are three main classes of immunoglobulins: IgM (macroglobulin), IgG (7*S* gammaglobulin—the common type of antibody), and IgA (7*S* gammaglobulin, which appears in secretions). Different types of antibody have different biological properties and are detected by different means.

Gel Precipitation.—Many antibodies precipitate with their corresponding antigen when they are mixed in the right proportions. When serum containing antibody diffuses towards antigen in an agar plate precipitin lines may form where the antibody and antigen meet. This method will detect antibodies against antigen occurring in the liver and many other organs in Sjögren's disease. Large amounts of antibody against thyroglobulin can sometimes be found with this method in Hashimoto's thyroiditis.

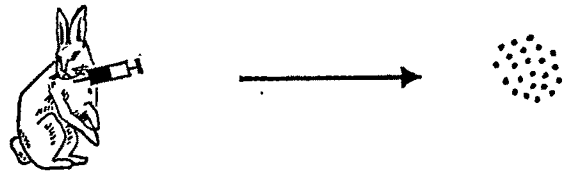
Tanned-red-cell Haemagglutination.—The precipitation test can be made very sensitive if the antigen is attached to an inert carrier such as a red blood cell. An important example is the tanned-red-cell technique for measuring autoantibodies to thyroglobulin. When sheep red cells are treated with tannic acid their surface is altered so that thyroglobulin will adhere. The tanned red cells coated with thyroglobulin are agglutinated by autoantibodies to thyroglobulin. These antibodies may show titres up to several million in Hashimoto's thyroiditis. This technique can be used to detect antibody against heart in the post-cardiotomy syndrome, and against muscle in myasthenia gravis.

Latex-fixation Test.—Antigen can also be attached to latex (rubber) particles, which are then agglutinated by antibody. Latex particles coated with human gammaglobulin are agglutinated by the rheumatoid factor (commonly found in the serum of patients with rheumatoid arthritis), which behaves like an antibody to altered human gammaglobulin.

In the *Rose-Waaler reaction,* sheep red cells are coated with rabbit gammaglobulin by mixing them with a subagglutinating amount of rabbit anti-sheep-red-cell serum. These cells are agglutinated by those rheumatoid factors which react with animal gammaglobulin. (See Fig. 2.)

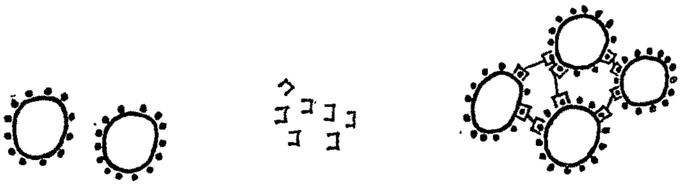
Complement Fixation.—When certain antibodies combine with antigen the resultant complex will react with a group of factors in fresh mammalian serum which are collectively known as complement. Sheep red cells coated with antibody are lysed by complement and are used as a detector system to show whether complement fixation has occurred. The complement-fixation test is used to detect autoantibody against thyroid cytoplasm, stomach, and adrenal gland in Hashimoto's thyroiditis, pernicious anaemia, and Addison's disease. These are examples of organ-specific autoantibodies.

FIG. 2.—Mechanism of the Rose-Waaler reaction for rheumatoid factor.



Rabbit is given injection of sheep red cells.

Antibody is produced against sheep red cells.



Sheep red cells are coated with a subagglutinating amount of rabbit antibody (7S, IgG) to sheep red cells. The antibody is altered by the act of combining with the sheep red cells.

Rheumatoid factor in patient's serum.

The coated sheep red cells are agglutinated by the rheumatoid factor present in the serum of many patients with rheumatoid arthritis. This is usually a macroglobulin antibody, and reacts with altered gammaglobulin.

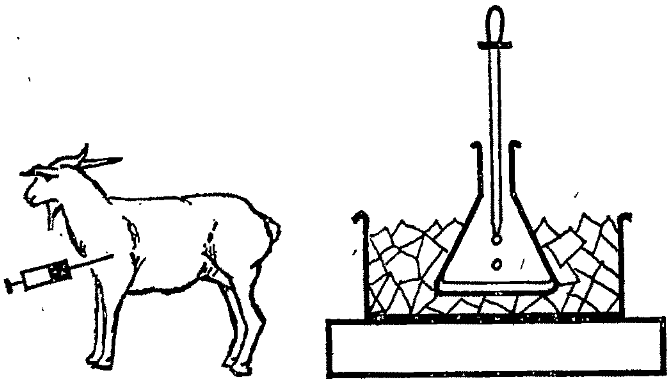
The Rose-Waaler reaction is sometimes called the sheep cell agglutination test (S.C.A.T.) or the differential agglutination test (D.A.T.).

Complement-fixing autoantibodies can also be demonstrated against a widely distributed antigen which occurs in liver, kidney, and many other organs. This is called the *autoimmune complement-fixation test* and it is an example of a non-organ-specific autoantibody. These autoantibodies are found in many patients with systemic lupus erythematosus, primary biliary cirrhosis, lupoid hepatitis, and Sjögren's disease, and in a few patients with rheumatoid arthritis and idiopathic pulmonary fibrosis.

Autoantibodies which react with the Wassermann antigen (alcoholic extract of beef heart) in some patients without syphilis are responsible for the biologically false-positive reaction. Transient biologically false-positive reactions are sometimes due to infection, such as glandular fever or infectious hepatitis, but about a sixth of all patients with chronic biologically false-positive reactions (positive reactions for over six months, with a negative treponema-immobilization test for syphilis) develop serious disease resembling rheumatoid arthritis or systemic lupus erythematosus.

FIG. 3.—Immunofluorescence.

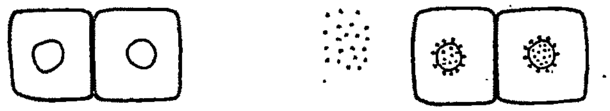
I. Preparation of Fluorescent Antihuman Gammaglobulin.



Antihuman gammaglobulin is prepared by injecting purified human gammaglobulin into a goat or rabbit.

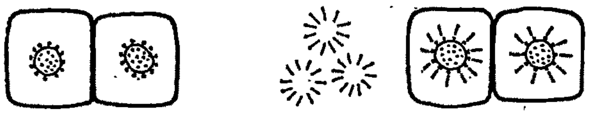
The serum is conjugated with fluorescein isothiocyanate.

II. Immunofluorescent Test for Antibody to Nuclei.



Tissue sectioned in cryostat to prevent damage to antigen. In some cases specially prepared paraffin sections can be used.

Serum containing antinuclear factor is applied to the section. Antibody (human gammaglobulin) adheres to the nuclei. The section is then washed.



The section is treated with fluorescent rabbit or goat anti-human gammaglobulin. This adheres to the sites where human gammaglobulin has combined with the nuclei. The section is examined under ultraviolet light. The nuclei give an apple-green fluorescence.

NOTE:

(1) Immunofluorescence may also be used to detect the site of binding of complement. The section is treated with human serum and complement (fresh human or guinea-pig serum) and the adherence of complement is detected by a fluorescent anticomplement serum. This is a microscopic complement-fixation test.

(2) Bound gammaglobulin refers to gammaglobulin found in sections which have not been treated with human serum in vitro. Immunoglobulins can be shown in antibody-producing cells. In other sites the finding of bound immunoglobulin provides some evidence of an in vivo antibody-antigen reaction if the gammaglobulin is unaccompanied by other serum proteins.

(3) Specific antisera can be prepared against different human immunoglobulins—such as IgG, IgA, and IgM—and these can be used to distinguish between different types of antibodies by immunofluorescence.

Immunofluorescence.—Immunofluorescence (Coons technique) is based on the fact that antibodies are gammaglobulins and are good antigens (see Fig. 3). Rabbits immunized with human gammaglobulin produce antibodies which react specifically with human gammaglobulin. These rabbit antisera can be conjugated with fluorescent dye, such as fluorescein, and used to detect human gammaglobulin.

Many autoantigens survive freezing of tissue and being cut into histological sections in a specially refrigerated cabinet or *cryostat* (at −20° C.). The sections are treated with serum being tested and then with the fluorescein-conjugated antihuman gammaglobulin. Microscopic examination in ultraviolet light shows fluorescence wherever the autoantibodies adhere.

Immunofluorescence is used to detect antibodies against nuclei—antinuclear factor. These are found in nearly all patients with systemic lupus erythematosus, and in many patients with lupoid hepatitis and Sjögren's disease, and in a variable number of patients with rheumatoid arthritis, polyarteritis nodosa, scleroderma, and dermatomyositis. Antibodies against the cytoplasmic constituents of thyroid, stomach, and adrenal can be demonstrated in diseases of the Hashimoto group. Antibodies occur against salivary-duct cells in Sjögren's disease, against heart and muscle in myasthenia gravis, and against mitochondria in primary biliary cirrhosis.

Immunofluorescence can be adapted to recognize the three types of immunoglobulin (IgM, IgG, and IgA) and complement-fixing antibodies. It can be used to detect gammaglobulin and complement which has become bound to human tissue *in vivo.* This uncommon occurrence provides some evidence of *in-vivo* antibody-antigen reactions. Bound gammaglobulin is found in the auricle of the heart in some cases of rheumatic fever, and in the kidney in systemic lupus erythematosus and many cases of nephritis.

Coombs Consumption Test.—Antibody against human gammaglobulin is known as *Coombs reagent.* The *Coombs consumption test* is an ingenious method of measuring antibody. Particulate antigen is mixed with the test serum and then washed repeatedly. It is assumed that antibody will adhere despite repeated washing, while non-specifically adhering gammaglobulin will be washed off. The ability of the treated particulate antigen to reduce the titre of an antihuman-gammaglobulin serum (Coombs reagent) is then measured. Some workers have found antibody against joint tissue in rheumatoid arthritis by this means.

(Part II of this article, with References, will appear in next week's issue.)

TODAY'S DRUGS

With the help of expert contributors we publish below notes on a selection of drugs in current use.

Prevention of Motion Sickness

Many factors are concerned in the production of motion sickness. Travel by sea or air may not affect those in whom a car journey induces violent symptoms, and the same stimulus may not cause motion sickness in a given individual on successive occasions. Visual and olfactory stimuli may precipitate nausea and vomiting, and without doubt psychological factors are often involved and may be "trigger" mechanisms in susceptible people. The final common pathway seems to involve a labyrinthine response, as patients whose vestibular function has been abolished by disease or surgical procedures are not subject to motion sickness.[1] This view is also supported by the observation that simultaneous movement in two planes can be used as an experimental tool in the production and study of this disorder.[2]

Controlled Trials

With so many variables the design of controlled trials of drugs in the prophylaxis of motion sickness has proved extremely difficult. Many of the available reports are of little value, as adequate controls have not been employed or the exposure of subjects to test conditions has not been matched to the period of maximum effect of the drug used. In a detailed and critical review of the methods available for the study of this problem Brand and Perry[3] concluded that "there is only one valid way of determining whether a compound is effective as a treatment for motion sickness and that is to test it in a properly designed field study in man." It is unfortunate that the failure to perform "properly designed" field studies has so often vitiated the conclusions of long and laborious exercises in clinical pharmacology.

Recent developments in intercontinental and space travel have given an urgency to the quest for effective prophylaxis, and several groups of American workers are engaged in studying this problem. The need for standardized test conditions has led to the development of new techniques. Of these the human centrifuge, a slowly rotating room in which subjects perform stereotyped head movements in a plane at right angles to that of rotation, has recently been described, and it has been claimed that this produces adequate and reproducible stimuli comparable to those existing in the natural situation.[4] Other attempts to produce standard conditions have led to the use of different types of swing, and in Great Britain to the testing of subjects exposed to artificial waves.[5] In all of these designs, where motion is orderly and predictable, some measure of habituation may occur, and care must be taken to ensure that the drugs tested are administered in a random sequence and compared with a placebo and no treatment at all.

Drugs With Proved Efficacy in Prevention of Motion Sickness

Drug (Group and Approved Name)	Adult Dose	Duration (hours)	Some Proprietary Preparations and Presentations
Phenothiazine antihistamines			
Promethazine	25–50 mg.	4–6	Phenergan tabs. 10, 25 mg.
Promethazine chlorotheophyllinate	25 mg.	4–6	Avomine tabs. 25 mg.
Ethanolamine antihistamines			
Diphenhydramine	50 mg.	4–6	Benadryl caps. 25 mg.
Dimenhydrinate (Diphenhydramine chlorotheophyllinate)	50 mg.	4–6	Dramamine tabs. 50 mg.
Piperazine antihistamines			
Cyclizine	50 mg.	6–8	Marzine tabs. 50 mg. Sereen tabs. 50 mg.* Valoid tabs. 50 mg.
Meclozine	50 mg.	12–24	Ancolan tabs. 25 mg. Sea-legs tabs. 12·5 mg.
Hyoscine	0·6 mg.	1½–3	Kwells tabs. 0·3 mg. Travel tabs. 0·3 mg.

* "Sereen" was formerly Boots' proprietary preparation of hyoscine 0·3 mg. Since 1958 the name has been given to the tablet form of cyclizine 50 mg.

Despite all these difficulties certain facts have been established, and a few drugs have demonstrated their efficacy consistently in controlled trials. The most important are considered individually below.

However, it should be emphasized that the essence of therapy in motion sickness lies in prophylaxis. Once nausea and vomiting are established no single drug is completely effective in relieving the symptoms. Vomiting may cause the rejection of swallowed tablets, and drugs may have to be given by injection to control symptoms at this stage.

Moreover, much can be achieved by attention to general measures and by avoiding precipitating situations. Car sickness in children is probably the most prevalent form of motion sickness and can often be reduced by frequent stops, adequate ventilation, and the avoidance of travel immediately after a meal. There is a tendency for children to "grow out" of a predisposition to motion sickness, but even in those who do not these common-sense precautions and the use of appropriate doses of prophylactic drugs will usually reduce the problem to manageable proportions.

Specific Drugs

Antihistamines

Promethazine.—This compound is a phenothiazine derivative with antihistamine properties. An oral dose of 25–50 mg. commonly produces drowsiness, which precludes use of the drug when activity and alertness are required. Its duration of action lies between four and six hours, the effect appearing after about 30 minutes. For prolonged prophylaxis it may be given twice or thrice daily.

A closely related compound, *promethazine chlorotheophyllinate,* is also available in 25-mg. doses, but appears to offer no specific advantage over promethazine in controlling symptoms. Neither of these drugs provides completely reliable prophylaxis, but both have been shown to be of value on prolonged journeys, where some degree of sedation is an acceptable side-effect.

Diphenhydramine and its Chlorotheophyllinate Derivative, Dimenhydrinate.—These are ethanolamines with antihistamine properties. Their duration of effect is similar to that of promethazine, and both have proved highly effective in preventing motion sickness. Side-effects may limit their use in some cases, as both produce drowsiness and occasionally vertigo.

Cyclizine and Meclozine.—These are antihistamines of the piperazine group. Of the more recent drugs available for the prevention of motion sickness these are the most effective. Cyclizine in a dose of 50 mg. has proved of value in car, air, and sea travel, is effective for up to six or eight hours, and has a low incidence of side-effects. The most prominent is sedation, but this is less frequent and intense than with many other antihistamines.

Meclozine, in a dose of 50 mg., has the longest duration of effect of the drugs considered here, and has been shown to act for at least 12 and sometimes up to 24 hours. Although it may cause slight sedation, it provides prolonged prophylaxis, and is probably the drug of choice when this is required.

Some years ago it was suggested that cyclizine and meclozine, which have been employed in pregnancy sickness, might be responsible for foetal abnormalities. A prolonged investigation, both by the manufacturers concerned and by independent medical research workers, has not established any definite hazard. However, the decision to use antiemetic or any other drugs in pregnancy should be taken only after careful consideration leads the prescriber to conclude that their use is essential to the patient's well-being.

All the above drugs are antihistamine compounds and may be bought freely. Some of the proprietary preparations and their doses are shown in the Table. Drugs in this group may all give rise to symptoms of parasympathetic blockade. The results are seldom severe enough to be unpleasant, but dryness of the mouth, blurred vision, and urinary difficulties have all been reported and presumably result from this atropine-like action. Gastrointestinal side-effects are occasionally seen but are unlikely to be troublesome with the relatively small total doses used in preventing motion sickness.

Hyoscine

This drug has emerged with a clear advantage from every controlled trial that has been designed to test the efficacy of drugs in the *short-term* prevention of motion sickness. The desired protection is achieved rapidly, in some cases within 20 minutes of administration, and lasts for up to three hours, but the actions of hyoscine on the parasympathetic nervous system are such that its side-effects are often more prominent than those of the antihistamines. Drowsiness, difficulty in accommodation, and dryness of the mouth may all occur, and in the elderly this compound may cause mental confusion.

In an attempt to reduce the sedative effects to a minimum hyoscine has been given with amphetamine, and it is claimed that this combination is highly effective. These claims are at present unsupported, and any drug combination containing amphetamine is of itself open to objection.

Other Preparations

Many other compounds have been advocated for the prophylaxis of motion sickness. Barbiturates have little specific effect, but produce sedation, and may allay anxiety. The phenothiazines, including chlorpromazine, which are of considerable use in the management of nausea and vomiting from other causes, have virtually no effect in motion sickness, and other drugs with tranquillizing actions are of no proved value, although they may possibly be useful in reducing anxiety. Although often included in proprietary mixtures, vitamins of any group have no effect in the prevention of motion sickness.

Undesirable Effects of Drugs

The possible consequences of taking effective drugs must always be remembered and should be stressed to the patient. Alcohol consumed on the cross-channel ferry may potentiate the effects of drugs taken to combat motion sickness. Sedation and impaired visual accommodation may render a driver unfit for Continental roads. Individual susceptibility to side-effects, however, might be established by a test dose of the chosen drug taken some days before the projected journey.

The inevitable conclusion from a survey of the published trials of drugs in motion sickness is that for short-term prophylaxis hyoscine is superior to all other compounds despite its side-effects, while for longer journeys there is a clear place for the antihistamines. No single drug will guarantee protection in all cases, but appreciable benefit can usually be obtained.

Those who prefer older remedies which have not been subjected to controlled clinical trial are referred to an index of treatment for 1910, which advocates "tight clothing around the abdomen," "the prone position," and "iced champagne."

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Shock with Insertion of I.U.D.

Q.—*What is the mechanism of the shock that can occur with the insertion of an intra-uterine contraceptive device, and what is the appropriate treatment?*

A.—It has been known for a long time that some women will faint when the cervix is stimulated, as being grasped by a vulsellum forceps or by the passage of a sound through the cervical canal. Why it should happen with some but not all women is not known, but it may be that it is more likely in those who are apprehensive, even though the apprehension is not overt.

The stimulus to the cervix presumably sets up afferent stimuli, and on the efferent side the vagus slows, and may temporarily stop, the heart, with consequent cerebral anaemia. Prevention might be by reassurance and full explanation of what is to be done, and by avoiding the use of the device in those who are obviously anxious.

When "shock" occurs it is treated on the lines usual in a faint—e.g., laying the patient down, elevating her legs, injecting analeptics, and possibly external cardiac massage, though these more heroic measures should not usually be needed. Though the device once through the cervical canal is unlikely to be a continuing cause of the shock, it would seem sensible in such a patient to try some other form of contraception.

Blood Groups and Rhesus Immunization

Q.—*Is there any known association between rhesus negativity and one of the ABO blood groups?*

A.—There is no known association between these blood-group systems. On the other hand, there are some interesting observations on the influence of the ABO groups on immunization to the Rh antigen in rhesus-negative mothers.

Rhesus-negative subjects receiving Rh-positive blood are far less likely to form Rh antibodies when there is incompatibility in the ABO system than when they are given blood of the same ABO group. Further, immunization to the Rh antigen by Rh-negative mothers is less common when the infant is ABO incompatible with the mother. To put it another way, an ABO-compatible, rhesus-positive foetus is much more likely to immunize its Rh-negative mother than a foetus of different ABO blood group.

The explanation probably lies in the rapid removal of ABO-incompatible cells from the recipient's circulation by either anti-A or anti-B present in serum, in much the same way that rhesus sensitization is prevented by clearing Rh-positive cells from the circulation by administering a serum containing anti-D.

Virus Infections

Q.—*Is there any evidence to suggest that virus infections are more common and more severe because antibiotic suppression of the bacterial infections has left the viruses a clearer field?*

A.—There is no evidence to support a belief that virus infections are more common than they were before antibiotics became available for therapy. It is true that some virus infections have become more prominent, but that is because more attention has been focused on them and their recognition and investigation have become possible as the result of great advances in the laboratory.

Book Reviews

Dangers in Food

Toxicants Occurring Naturally in Foods. Food Protection Committee, Food and Nutrition Board, National Academy of Sciences, National Research Council. (Pp. 301. $6.00.) Washington: National Research Council. 1966.

To control food production so that no known toxic additives or contaminants enter human food is difficult, but it would seem impossible at the present time to prevent consumption of toxic materials that occur naturally in food. The widespread occurrence of toxic materials is illustrated by the book under review, which is a compilation of 27 chapters by different experts commissioned by the Food Protection Committee of the U.S. National Academy of Sciences.

The many subjects discussed include goitrogens, oestrogens, carcinogens, lathyrogens, favism, haemagglutinins, cyanogenetic glycosides, stimulants and depressants, antigens and allergens, pressor amines, antivitamins, antienzymes, cholinesterase inhibitors, natural radioactivity, fungal toxins, seafood toxins, spices and flavours, unusual foods (including quail and ackee), vitamins, excesses of amino-acids, essential minerals, food fats, gossypol, nitrates and nitrites, oxalates, and the effects of sodium chloride in relation to the protective action of potassium. Although this list of subjects is long it cannot be considered as complete as bacterial toxins, narcotics, hallucinatory agents, and the possible effects of cholesterol on circulation are not discussed. This list of chapters illustrates the wide range of potentially harmful materials occurring in food. Many diseases in man, including cancer and mental diseases, could be due to natural foods. The difficulties of attributing a particular disease to any special food are great because people in developed and sometimes even in developing countries consume many different foods. The identification of toxic principles in food is a field of preventive medicine that requires more thought and investigation.

Most of the contributors in the volume are objective and cautious and stress the need for more information that can be gained only by research and epidemiological studies. Dr. M. Stob, however, writing about natural oestrogens, concludes that "consumption of any food product in quantity sufficient to cause a physiologic effect due to oestrogens it contains seems remote." Few studies of oestrogenic activity of human foods, however, have been made and the dose causing a "physiologic effect" in women is difficult to assess. The growth of hormone-dependent cancers may require minute quantities of hormone.

The book provides valuable accounts of toxic materials that occur in foods of many different countries. In addition to the scientific descriptions there are some legends, such as a charming account of the discovery of coffee by the "prior of an Arabian convent." The food protection committee and the many contributors are to be congratulated on producing an interesting and stimulating compilation at a reasonable price.

E. BOYLAND.

Common Skin Diseases

Treatment of Common Skin Diseases. Articles originally published in the Current Practice section of the *British Medical Journal.* (Pp. 116; illustrated. 10s.) London: British Medical Association. 1967.

Diseases of the skin account for some 10% of consultations in general practice. At least 80% of these patients are suffering from eczema, warts, acne, pruritus, psoriasis, tinea, or too much or too little hair. The therapeutic repertory of some practitioners is sadly limited; corticosteroids, often unnecessarily associated with the potentially sensitizing neomycin, tend to be prescribed indiscriminately as a panacea.

In this very modestly priced but attractively produced book the Editor of the *B.M.J.* has republished 14 articles which have recently appeared in its pages. All are sound and practical. Twelve chapters are concerned with common diseases, and experienced dermatologists provide clear guidance on their management based on long personal experience. Contact dermatitis deserved a longer chapter, and the material that has been competently but illogically and misleadingly compressed into a single chapter on "infectious eczemas" could have been more appropriately classified.

Two chapters are concerned with less common conditions, ichthyosis and lupus erythematosus. Both are excellent, and one can appreciate the Editor's reluctance to discard them in favour of chapters on scabies and pyogenic infections which, on account of the continued and increasing prevalence of these disorders, should have been included. These are the only important omissions.

The general practitioner will find this book authoritative, readable, and helpful. It can be recommended as excellent value for money.

A. J. ROOK.

Scientific Exploration of Development

Human Development. Edited by Frank Falkner, M.D., M.R.C.P. (Pp. 644 + xx; illustrated. £7.) Philadelphia and London: W. B. Saunders. 1966.

In a delightfully lucid foreword which needs no translating Professor Robert Debré introduces *"le livre sur le développement de l'homme, où le Professeur Frank Falkner a réuni tant de savants."* The subject and the savants cross international boundaries. The editor, with a background of research and long experience in co-ordination at the Centre International de l'Enfance, has welded the savants into an admirable team.

In this one book basic sciences and medicine are brought together and skilfully deployed. The title might well have been "Human Biology." As it is, from the twin-words "growth and development" the editor has dropped one because the accepted distinction between growth (the multiplication of cells and changes in size) and development (the maturation of structures and functions) is no longer tenable. "In other words," he writes, "the twins were in reality uni-ovular." "The subject of human development is in a rapid state of change. Some of its students cry forward to fewer data on more subjects and others cry back to more data on fewer subjects. This well-known state, if lucky, results in a fertile oscillatory tandem." After this quotation, from Tanner, Professor Falkner remarks "it is our responsibility as human biologists to remove the element of luck," and he and his colleagues show how it is being done.

I imagine that most clinicians, as I did, will find it difficult to stop nibbling from such an impressive selection of skilfully interrelated topics, but will continue to use the book as an essential source for reference. The basic early chapters deal with biological principles of growth, general considerations in human development, statistics, and developmental genetics. Subsequent chapters describe physiological growth and biochemical, hormonal, sexual, and nutritional influences. Informative sections on the development of the nervous system (before and after birth), of vision, bones and skeleton, face and teeth, are complemented by others, equally stimulating, on speech, language and hearing, psychology, cultural patterning (a fascinating description), and even immunology. The influence of family and social factors on intellectual development is one example of the good editing and synthesis throughout the book.

In scope and range, in erudition and readability, this forward-looking compilation will surely prove essential for both bedside paediatricians and back-room research workers. It will give enjoyment, too, to any doctor who is interested in the scientific exploration of the strange ways in which we humans grow.

JOHN APLEY.

An Old Friend—Unchanged

Hamilton Bailey's Demonstrations of Physical Signs in Clinical Surgery. 14th edition. Edited by Allan Clain, M.B.(Cape), F.R.C.S.(Eng.) (Pp. 627+x; illustrated. 75s.) Bristol: John Wright. 1967.

Hamilton Bailey's *Physical Signs* is well established as a pillar of clinical teaching. In its fourteenth edition, with 247,000 copies sold, it no longer needs a reviewer's commendatory pat on the back. Rather it impels one to be critical, to ask whether the book continues to maintain its own high standard, and how it should be judged as an instrument of teaching in the context of the present day.

The value of this book lies in its illustrations. Bailey, as a good clinical teacher, preferred pictures to words, but sometimes his zeal as a collector carried him away; he judged a picture by its attractiveness rather than its message, he retained old friends when they had ceased to be relevant, and he could not bring himself to dispose of duplicates. Consequently, some of his illustrations are out of place in a student's book, some are out of date, and many are out of proportion to the importance of their subject. Moreover, most teachers will now agree that the needs of clinical teaching have changed, and that, however important the spot diagnosis of lumps and bumps, it is at least as important to avoid emphasizing rarities.

Thus, Hutchinson's teeth, Clutton's joints, syphilitic dactylitis, empyema necessitatis, and osteomyelitis of the sternum should all go overboard. So too should go the monstrosities of surgical museums, the turban tumour, the puffy and peculiar tumours of Pott and Cock respectively, the cystosarcoma phylloides, and the dermatofibrosarcoma protuberans. So too such delineations of the obvious as the cauliflower ear, the bat ears, the genu recurvatum, and some of the nine pictures of exophthalmos. And it is debatable if even the photograph of a tape measure, a pleasing whim when introduced by the maestro, should be perpetuated.

Mr. Allan Clain, who has been responsible for this edition, acknowledges that devotion to a former chief has led him to initiate few changes, and his piety will be respected. But some radical amendments will be needed next time.

CHARLES ILLINGWORTH.

Psychiatric Campaigner

The Unquiet Mind. The Autobiography of a Physician in Psychological Medicine. By William Sargant. (Pp. 240+xvi; illustrated. 30s.) London: William Heinemann. 1967.

The main purpose of this book, the author says, is to describe the fascinating progress of medical and surgical treatments of mental disorders during the last three decades. The autobiographical method of presentation has always appealed to some clinical teachers, especially to those who experience their work as an unending personal battle against two monsters—disease and the ignorance of their colleagues. The successful ones among those campaigners are, like generals, apt to publish autobiographies.

The physical treatments of mental disorders about which Dr. Sargant writes with such fervour are used all over the world and have transformed the psychiatric scene. However, Dr. Sargant paints too rosy a picture of their effects. So enthusiastic is he about them that lay readers may be led to assume, mistakenly, that a therapeutic breakthrough comparable to the introduction of the antibiotics into the treatment of infectious diseases had taken place in psychiatry. Many of them will feel very angry about the psychiatrists who do not share the author's approach and whom he castigates so severely. In evaluating those methods he relies largely on his own clinical experience, because he "distrusts statistical reports on treatments by any writer for whose judgement and lack of bias he cannot personally vouch." He does, however, accept such reports if they concern treatments not favoured by him—for example, psychotherapy. There is, of course, more to psychiatric treatment than the use of drugs, shocks, and surgery, valuable though they are.

Among the various good causes the author has espoused and which he discusses in the book are the establishment of psychiatric departments in general hospitals and the reform of the criminal law relating to mental illness. The book is written in a breezy style and reads well. Some of the text might be too technical for the lay reader. The author is at his best when he describes his life and work under the London blitz, but his explanation of the differences between the outcome of neurotic reactions to combat stress in the two world wars is questionable.

Many of his friends, including the present reviewer, will feel that the author has not done himself justice. He is not really the intolerant, self-opinionated, and naive man he makes himself out to be in this book. He is, in fact, broadminded, modest, charitable of other people's shortcomings, and he respects all therapeutic approaches in psychiatry. Only when he is in a campaigning mood are those virtues less manifest. But this is the risk of an autobiography written on active service and under the influence of the mass media, when issues and events tend to be presented to the general public as either black or white and always as very simple.

CONTEMPORARY THEMES

Relevance of American Experience of Narcotic Addiction to the British Scene

GRIFFITH EDWARDS,* M.A., D.M., D.P.M.

Brit. med. J., 1967, 3, 425–429

The United States has had a large drug addiction problem for a long time. At present there are probably upwards of 60,000 narcotic addicts in the U.S.A. (O'Donnell and Ball, 1966), with New York alone perhaps accounting for half the total. In comparison the problem in Britain seems small, but the concern here must be not so much with the problem's present absolute size as with its rate of growth—from 57 heroin addicts in 1954, 521 in 1965 (Home Office figures), with by now perhaps 2,000 to 3,000, and extrapolation to 10 years hence suggesting a quite frightening figure. In planning our own response to this problem it is natural to turn for guidance to America's much greater experience.

But is American experience relevant to our own country's problem ? The gross disparity, diminishing though that gap may be, between the two prevalence rates immediately suggests that different processes may be at work. One obvious explanation for this disparity in addiction rates is the contrasting general level of social disturbance in the two countries, as shown by the data in the Table.

Some Indices of Social Problems in U.S.A. and England and Wales, 1964

	U.S.A.	England & Wales
Infant mortality (deaths under 1 year of age per thousand live births) ..	44·0	19·9
Illegitimate live births per thousand live births	121	72
Divorces granted during year per thousand population	2·3 (provisional figure)	0·7
Suicide per thousand deaths	12·0	10·4
*Murder per million population ..	48	6
*Robbery per million population ..	582	83·5 (incl. blackmail)

Data gathered from *Vital Statistics—Statistical Abstracts of U.S.A.* and *Annual Abstract of Statistics*, Central Statistical Office, H.M.S.O., London.

* For difficulties of comparison between criminal statistics of different countries, see *Cultural Factors in Delinquency*, edited by T. C. N. Gibbens and R. H. Ahrenfeldt, p. 87. Tavistock Publications, London, 1966.

Thus undoubtedly a large part of America's drug addiction represents one more manifestation of the problems stemming from poverty, city disorganization, and the failure of the United States to integrate into its larger society the Negro, the Puerto Rican, and the Mexican. Narcotic addiction is to a considerable extent overrepresented in ethnic subgroups (Vaillant, 1966). Work by Chein *et al.* (1964) has shown the close relation in New York between addiction rates and the " delinquent subculture " of areas of poverty. Moreover, drug-addiction rates in the Chinese inhabitants of New York are falling, the presumed explanation being that they are gradually becoming assimilated and are advancing their social status (Ball and Lau, 1966).

The differences between the U.S. and British scenes should certainly not be minimized. America, for instance, has an entrenched black market and greatly different legal provisions, while the addict is submitted to pressures towards treatment. Moreover, the absence of a national health service may bear on the ability of society to respond to a problem such as addiction. Nevertheless, to conclude that the explanation of American addiction is simply a matter for the sociologist would be wrong, for even in the very worst areas only a small proportion of those at risk become addicts. The general impression of American workers seems to be that although some fortuitous circumstance, some juxtaposition, may result in " the ordinary kid " becoming an addict, it is necessary to look at personality as well as the surroundings. Not all American narcotic addicts come from the grossly underprivileged sectors of society: America also has its white addicts of relatively privileged background, and Ball (1965) and Bates (1966) have shown how incorrect any description of the American addict would be which generalizes him into one stereotype. The tendency now is toward the delineation in America of several different types of narcotic addiction.

The history of narcotic addiction in the U.S.A. shows the rapidity and unpredictability with which drug-abuse patterns can change ; and here surely is something which comes very close to home. O'Donnell and Ball (1966) have shown that in the earlier part of this century the American addict was thought of usually either as a Chinese " dope-fiend " or quite often as a respectable middle-class citizen from a rural area, while in some parts of the country free prescribing of opiates for gynaecological disorders meant that female were higher than male addiction rates. The Chinese problem has faded out, addiction has become dominantly urban, the Negro and now the Puerto Rican have become heavily involved, and recently there has been growing alarm about the increased use of amphetamine, barbiturates, and tranquillizers, and the cult of using psychedelic drugs among college students and the emancipated. The vital lesson is that patterns of drug usage are not static. Even if some aspects of the American drug problem seem remote from our likely experience today, we must heed the warning that America's problems today may be ours of tomorrow.

Legal Provisions, Punishment, and Compulsory Treatment

In fulfilment of the U.S. Government's obligations as a signatory to the 1912 Hague Opium Convention, which required member countries to introduce legislation to control domestic production, sale, and distribution of opiates and cocaine, Congress in 1914 passed the Harrison Act. Schur

---

* Addiction Research Unit, Institute of Psychiatry, Maudsley Hospital, London S.E.5.

(1963) has argued that the original intention of this Act was not to remove the management of the addict from the doctor. He contends that it was the Narcotics Bureau's misinterpretation of the Act's provisions that led to the bringing into existence of a large "criminal class." In 1951 Federal legislation (the Boggs Act) introduced severe mandatory minimum prison sentences, and with the Boggs–Daniel Act of 1956 penalties were made even heavier—5 to 20 years for a first offence, and 10 to 40 years for a second or subsequent offence of unlawful sale, possession, or importing of narcotic drugs, and the possibility of the death penalty for selling heroin to anyone under 18. Marihuana is for legal purposes generally classed in the U.S.A. as a narcotic.

"Civil Commitment"

An important new trend in legislative policy has recently developed with the introduction, first at State and now at Federal level, of "Civil Commitments." California's Civil Commitment Programme was set up in 1961 after a court ruling that previous provisions which sought to make *criminal* the mere fact of being an addict, as opposed to possession or sale of drugs, was unconstitutional. California has something between 10,000 and 20,000 addicts, and the intention of this legislation was to enable the State to institute an effective policy for the first time.

Previously an obvious addict picked up on some petty offence such as stealing would have been back on the street after a short sentence, for the court could take no cognizance of his addiction. But under the new Act a person found guilty of a misdemeanour or non-violent felony, and identified as an addict, can be committed for up to seven years to the California Rehabilitation Centre programme, which is administered by the Department of Correction. Of this seven-year term, rather more than the first year is on average spent in a closed institution, where the emphasis is on counselling, work rehabilitation, and exploitation of a therapeutic milieu. The addict is then placed on parole with strict supervision and chemical testing. Any breach of parole—a positive urine test or naline test (Way *et al.*, 1963, 1966)—will result in his immediate return to custody. By mid-1968 it is expected that there will in California be an institutional population of just under, and an outpatient load of just over, 2,000 cases (Wood, 1967).

Civil commitment is now also being introduced under the 1966 Federal Narcotic Rehabilitation Act (U.S. Government, 1966), and on 1 April 1967 an ambitious State civil commitment scheme began to operate in New York (State of New York, 1966). But for much of this legislation time is required to determine how the law will work in practice, and to see what interpretations will be made by the courts.

The questions of whether the addict is to be regarded as a patient or as a criminal and of whether narcotics should be legalized or still harsher laws enacted, have produced in the U.S.A. a debate of quite dramatic acerbity, despite a remarkable dearth of evidence on which to base assertions. A publication of the Federal Narcotics Bureau (U.S. Treasury Department, 1966) urges that "much effort needs to be exerted to have both the heavy penalties and compulsory hospitalization extended to every part of the United States." Chein, on the other hand, has argued that the worst consequences of addiction result not from the drug but from public policy towards the user, and it has been pointed out that the addict, risking his life every time he takes heroin, is not in the nature of logic particularly likely to be deterred by harsh penalties (Narcotics Conference Report, 1963).

Though this American debate on compulsion is highly relevant to the British scene, the central issues require clarification. Two separate questions are involved: firstly, whether harsh legal measures can prevent addiction, and, secondly, whether compulsion can be of help in the treatment of the individual.

Effects of Strict Legislation

National figures on the drug addiction rate are not sufficiently accurate or sensitive to reflect time trends or the influence of specific legislative measures. Strict laws in Ohio cut down narcotic convictions by 80%, but, to quote the Narcotics Bureau (U.S. Treasury Department, 1966): "Of course, some of the racketeers moved their dirty trade into more easy-going States." Champions of the punitive approach can argue that the problem in America would have been even worse if the law had been more lenient, but this is no more than speculation. Moreover, legislation there, aimed specifically at "the pedlar" rather than at the addict, seems to have proved relatively unsuccessful, partly because the two are often one and the same person and partly because the really high-level criminal is seldom convicted.

Thus, on reviewing the American experience, vindictive legislation is apparently not a successful method of preventive medicine. The important lesson for Britain is that, despite more than 40 years of punishing the addict, America still has a large drug-addiction rate, a well-established black market, and an addict population which is forced into varieties of criminality.

Compulsion in Treatment

Considering the role of compulsion in assisting in the treatment of the individual patient, one finds that the evidence is perhaps rather disturbing in its bearing on current British policy. Vaillant and Raisor (1966) reported a 12-year follow-up on 100 addicts discharged from the Federal hospital at Lexington. Because many of these patients had over the years undergone, in more or less random sequence, voluntary hospitalization, short- or long-term imprisonment, or imprisonment and parole, the authors were able to identify groups of patients who had as it were acted as their own controls. Patients were usually seen at three-monthly intervals by social workers whose prime aim was to obtain follow-up information, but who also offered social-work help. One-year abstinence rates following the different "treatments" were as follows: hospitalization 4%; short-term imprisonment (less than nine months) 4%; long-term imprisonment (more than nine months) 13%; imprisonment plus subsequent parole supervision 67%. The efficacy of probation is supported by the most recent report on the California Programme (Wood, 1967), which states that 34% of men on probation have not taken drugs for a year.

Does probation backed by effective threat of reimprisonment therefore offer excellent hope while other methods give derisory results? The intepretation of Vaillant and Raisor's important study should be more guarded than this, and it must be emphasized that they were comparing very vigorous probation supervision with community care which must often have been far from intensive.

Nevertheless, there seems to be a strong feeling among experienced workers in the U.S.A. that an element of coercion is necessary (Maurer and Vogel, 1967; Lieberman and Brill, 1967). Here, then, is a dilemma—repressive legislation appears to be an ineffectual and dangerous public health measure, and yet the threat of imprisonment seems to increase the chances that the probated addict will respond to treatment. How is Britain to solve this dilemma?

A Solution in Britain?

The only way of determining whether in Britain treatment can be successful without compulsion is to try intensive-treatment programmes in the setting of present law, and carefully to assess the results which are obtained. For a proper judgement such treatment must be skilled and energetic, and one can predict at the outset that voluntary treatment will *appear* to be ineffective if the treatment under consideration is lackadaisical, carried out by medical staff with too many other commitments, and unsupported by adequate social work and rehabilitative services—in other words, treatment which focuses on detoxification rather than on the needs of a troubled person. In summary, therefore, rather than focusing energies and attention on reshaping the law, the whole lesson of the American scene in this respect would seem to be that we should act now while the problem is still relatively a small one, and set up the very best possible treatment services so that voluntary methods will be given more than a handicapped chance to prove their worth.

Heroin Dispensing and Alternatives to Heroin

In 1919 following a Supreme Court decision which appeared to indicate that the private physician who prescribed maintenance drugs to his addict patient would be risking prosecution, a number of special narcotic dispensaries were set up to cope with the needs of addicts suddenly deprived of their supplies. By 1923, however, the last of these dispensaries was closing down, and the experiment was generally being pronounced a failure.

What really happened ? Though the American Medical Association (1963) has attempted to answer this question, it seems that proper data on the experiment were never gathered. The clinics closed partly because of medical pressure and partly because of opposition from the Narcotics Bureau ; most clinics made no attempt at treatment but simply handed to the addict his drugs. Diversion of narcotics to other than registered addicts occurred and there were complaints that criminal elements were being attracted to the areas of town where the dispensaries were situated.

If the role of the clinics envisaged in the British legislation (House of Commons, Dangerous Drugs Bill, 1967) should degenerate into a mere handout centre, it is likely that the American experience would be repeated. Thus it is vitally important that the staff of the clinics which are being set up under the 1967 Act should be concerned with and involved in the total treatment programme, should have as their aim to woo the addict off drugs, and must have immediately available facilities for detoxification and later rehabilitation, so that, when the addict shows interest in treatment, treatment can be provided. The doctors staffing these clinics cannot be part-time clinical assistants unsupported by psychiatric training.

Even if the new British clinics are adequate for the purpose the policy of heroin prescribing will still face very considerable difficulties, inherent in the properties of the drug itself. The American evidence seems to suggest that its pharmacology weighs heavily against the possibility that most of our addicts will be safely maintained on a fixed dose of heroin, will return to social functioning, and be prevented from diverting their supplies to the black market (Wikler, 1952 ; Fraser *et al.*, 1963).

Maintenance Dosage

American studies also throw some light on what is one of the essential assumptions underlying the new British policy—namely, that an individual, satisfactory, fixed maintenance dose can be determined for any particular addict so that he will receive enough not to be tempted to patronize the black market, while at the same time he has no excess to sell or proselytize. Work by Martin and Fraser (1961) has shown that the patient may be in pharmacological balance—receiving the " correct dose " so far as the doctor is concerned—but may still, in the patient's judgement, be requiring more of the drug. Moreover, under a policy which seeks to stop the addict from turning to the black market, if doctor and addict disagree on " need," then the addict must be the arbiter. One way of preventing over-prescribing might be to rely on chemical assay methods. Urine levels will, however, largely reflect only the time at which the last injection was given, and a person with a considerable drug dependency might some time after the last injection show a near zero blood level. No doubt some technique could be worked out, but it is difficult to believe that such methods could easily be applied to the routine work of a drug maintenance clinic.

Hence research in America suggests that maintenance drugs will have to be given under the strictest supervision. Because heroin is a short-acting drug this will entail injections three or four times a day, and the demands on the staff at the clinic and on the patient in terms of travelling time are going to be considerable. Thus in reality either the drug will have to be given daily into the patient's own hands, or a supply of prescriptions will have to be deposited with a chemist for daily dispensing. In either case the possibility of black-market diversion is opened up again, while the fact that the patient is continuing to give his own probably unsterile injections carries the likelihood of more than occasional tragedy.

Whatever the theoretical arguments, only close observation of the actual running of the new clinics will give the answers—whether patients can be maintained successfully on a fixed dosage schedule, whether for most addicts less than optimal supplies of safely and legally obtained heroin are an acceptable alternative to escalation and seeking drugs on the black market, whether diversion of supplies to illicit distribution continues, whether training in sterile injection techniques can decrease the incidence of infections. But American evidence is not encouraging—heroin for maintenance is a bad choice of drug.

Other Drugs for Maintenance

Could any other drug be used ? Dole and Nyswander (1965, 1966, 1967) have shown that methadone (Physeptone) is sometimes an acceptable alternative to heroin. The obvious advantages of methadone are that it is a long-acting drug and therefore given only once a day, that it can be taken orally, and that in daily doses of 80–120 mg. it blocks the euphoric effect of any other narcotic which is coincidentally taken, but does not in itself produce psychological or motor effects which impair social functioning. This interesting work has been criticized on several grounds, some of which are ill-founded, and there is an obvious need for continuing, careful assessment of the results of treatment.

The development of a series of N-substituted benzo-morphan derivatives may be of particular importance—for example, cyclazocine, which experimentally has been shown to be able to block the effects of morphine in daily doses up to 240 mg. (Martin *et al.*, 1966) and which in clinical practice is also of some value (Jaffe and Brill, 1966). The hope is that drugs can be developed which, unlike methadone, do not subject the addict's system to the continuing experience of narcotic intoxication but which relieve drug hunger and drug-seeking activity—cyclazocine itself, though given orally, is perhaps too short-acting to provide the ideal answer. Patients may find that by taking cyclazocine during the week and stopping it at week-ends they have a way of " chipping " without becoming " hooked."

Two important differences should be noted between the American and British scenes so far as drug substitution is concerned. Firstly, in Britain addicts take a much higher heroin dosage than in America and the efficacy of substituting or blocking drugs is not so certain. Secondly, in America the choice facing the addict is between easily available methadone and expensively, criminally, and dangerously obtained weak heroin, whereas in Britain the choice is between free methadone and free, good quality, safely and legally obtained heroin. Only experience will show how many addicts genuinely want to give up heroin but, despite their intentions, find the task of remaining abstinent too difficult. Any change in the law that sought to make methadone a drug which the doctor could prescribe without the addict's choice being consulted would have sound pharmacological argument on its side, but at present would probably result in a considerable number of addicts turning to the black market.

Hospitals and Alternatives to Hospitals

In the U.S.A. generally there is a mood of disillusionment regarding the role of conventional psychiatric inpatient ward care in the treatment of drug addiction. If there is no compulsion the patient discharges himself, and if there is compulsion then the patient and staff work against each other, or, worse still, the patients learn to "give the right answers." And yet there is the feeling that if the addict is to have any hope of successfully breaking with his habit and with the life pattern of the addict–criminal subculture he requires a period in a controlled environment right away from the street. This argument is supported by evidence that in the rat physiological changes persist for at least six months after heroin withdrawal (Martin *et al.*, 1963) and by Wikler's (1965) theory, which emphasizes the importance of conditioning factors in opiate addiction and relapse.

The way out of this particular dilemma seems to be to provide the initial period of "control and removal" in some sort of therapeutic community, either within the hospital or prison, or in some quite other facility unrelated to conventional institutions. In this both Synanon and Daytop have clearly played a major part in making people think again.

Synanon was started in 1958 (Casriel *et al.*, 1963) and today is a community of 700 former addicts who live without drugs and without locked doors. The community owns a fleet of cars and trucks, threatens to buy an aeroplane, runs businesses, has its own dance band, and bids fair to becoming one of the great American success stories. The brashness and aggressiveness of some of Synanon's claims have drawn criticism, and the critic can rightly point out that records which would allow proper assessment of results are not available, that because no urine testing is allowed validation of all claims is uncertain, and that Synanon may be similar to the methadone programme in that it takes an atypical addict. A visit to Synanon and time spent casually talking to its residents strongly suggests, however, that whatever the ultimate statistics this organization is achieving very remarkable successes. The importance of Synanon is not only in terms of the count of addicts helped, but also lies in what psychiatry has to learn from the methods of treatment which the community has evolved (Holzinger, 1965). Daytop village in New York (Shelly and Bassin, 1965), based on the Synanon model, seems to be achieving similar success ; but in Daytop, unlike Synanon, many of the residents are under the coercion of a probation order.

The most interesting departures which Synanon and Daytop have made from the usual psychiatric approach to drug addiction include their emphasis on the addict not being ill but his being "stupid" and "a baby." Emphasis is on feeling rather than on cognition. The communities make no pretence at democracy, and the confusion regarding role and authority structure which can so easily occur in psychiatrically run models of the therapeutic community has in Synanon and Daytop been avoided. Interreaction in group discussions is often verbally violent and brutally frank, but there is also an emphasis on mutual concern—"you really have to love people, not just want to help them like a social worker."

Could a Synanon or Daytop function in Britain ? There would seem to be no inherent reason why such an experiment should not succeed here, and the influence of the experiment on the whole scene might be important, forcing rethinking and imagination. The idealism, energy, and sheer fun of such communities may be more able to win the interest and loyalty of the young addict than can the "square" world of the mental hospital.

Community Centred Programmes

In the organization of psychiatric care the general American trend is toward provision of community-based services (Glasscote *et al.*, 1964 ; Ozarin and Brown, 1965), and thinking on the services for the narcotic addict follows this direction. Those authorities who advocate the initial period of "control" within a closed institution or Synanon type facility would probably all agree that there is no value in this period of removal from society unless on return to society continued help is given. Nevertheless, Vaillant and Raisor (1966) showed, with the particular group of addicts studied and with the community services of rather heterogeneous and uncertain intensity, that only small success could be expected from community care without coercion.

Though caution is necessary in applying experience to Britain, several U.S. experiments in community treatment of addicts are worth mentioning, particularly that of Dr. Efron Ramirez, in Puerto Rico (Ramirez, 1966). This rather startlingly reverses the usual phases of treatment: community care starts the treatment and only later is inpatient therapy offered. The induction phase—"a training process for future treatment"—lasts two to three months and comprises the street encounter, a sort of day hospital programme, and then detoxification. Ramirez believes that the best person to win the addict into treatment is the recovered addict, and it is the recovered patient who goes out on to the street to look for new clients, and the "training for treatment" then continues "in a store front office in a neighbourhood of high drug incidence." The period of residential treatment which follows is expected to last 10 to 12 months, and this is followed by a year in a "re-entry house," in which control is looser and there is gradual resumption of everyday life in the community. Ramirez has now moved to New York, where he is Co-ordinator of Addiction Programmes.

Several other influential but more orthodox community orientated projects have been based on and linked with hospital outpatient departments: the New York Demonstration Centre (Brill, 1965) ; the programme run by the Metropolitan Hospital Centre (Brotman *et al.*, 1965) ; the Washington Heights Rehabilitation Centre (Brill, 1966). The Greenwich Village Counselling Centre (Osnos and Laskowitz, 1966) and the Special Problems Centre in San Francisco have shown the feasibility of treating narcotic addicts and non-addict clients in the same premises.

Conclusions

The growing rate of drug addiction in Britain (Bewley, 1966) has forced revision of the law, but the underlying philosophy which guides the British approach remains unaltered: the thesis was and is that the interests of treatment and prevention are best served by regarding the addict as a patient, by giving him heroin if he so demands, by wooing him rather than coercing him into treatment, and by keeping addiction above ground rather than by driving it into the criminal underworld. The next few years will show whether this philosophy can be the basis of a viable policy. There is nothing in the American experience which guarantees failure, but much to suggest that we are playing against long odds—heroin is a bad and unpleasant drug for maintenance, and to hope that without any form of coercion the addict can be persuaded to abandon freely available narcotics is ambitious indeed. The whole of American experience would suggest that if our new programme is to be other than foredoomed to failure and a prelude to debacle, it must be conducted with vigour and energy, must be a matter of reaching out rather than of sitting back in hospitals, must focus on human needs and rehabilitation rather than on drug maintenance or detoxification. Saving of money at this stage may prove a costly economy.

As for research, the important focus in Britain as in any other country must be on finding why people become addicts and on discovering how they can be aided to recovery: the most profitable focus is likely to be on the society and the person rather than on the drug. Addiction research is nothing special: it is part medical and psychiatric research, and if the experts become isolated work will suffer. The study of schizophrenia, of the alcoholic, of the recidivist, exploration of the effective elements within psychotherapy, the wide and general field of psychopharmacology—all this is germane.

If there is one final lesson to be learnt from all of those who have been grappling with the problem of drug addiction in America for years, it is that discussion in these highly charged and disturbing matters should remain open—that rationality should prevail.

This paper is based on the experience of an eight-week trip to the U.S.A. and on discussions held with many people who with the greatest generosity and courtesy gave their time. To all of them I would like to express my warm and personal gratitude. My particular thanks are due to Dr. Stanley Yolles, Director of the National Institute of Mental Health, Washington, and to Dr. Sherman Kieffer and Dr. Tom Cassidy. The sponsorship of the National Institute of Mental Health made this trip possible. I would like to thank my secretary, Mrs. Julia Polglaze, and Miss Elsie Hoffmeister.

MEDICAL ETHICS

Supervision of the Ethics of Clinical Investigations in Institutions

Report of the Committee Appointed by the Royal College of Physicians of London[*]

Following the receipt of a letter on 5 September 1966 on this subject from certain Fellows, the College appointed a committee to consider how far supervision of clinical investigation was required, and, if it was required, how best it might be effected.

The term "clinical investigation" is regarded by the Committee as covering all forms of experiment on man. There are broadly two kinds of clinical investigation or research. The first is that which has direct diagnostic or therapeutic relevance to the individual patient and which therefore seldom poses serious ethical problems. Indeed the doctor could sometimes be said to have failed in his duty to his patient if he did not perform such an experiment.

The second kind of investigation or research is that which is carried out to advance knowledge, and from which the subject, be he a patient or a normal person, cannot expect direct personal benefit. This kind of clinical investigation benefits the community, but may present difficult ethical problems in relation to the individual.

The design and conduct of clinical investigation should be guided by a code of ethical practice, and the Code of Ethics of the World Medical Association (Declaration of Helsinki) is accepted throughout the civilized world. The Medical Research Council has also issued a statement on "Responsibility in Investigations on Human Subjects" (M.R.C. Annual Report, 1962–3. Cmnd. 2382, H.M.S.O.). This has been reprinted, together with the Declaration of Helsinki, in the *British Medical Journal* (1964, 2, 177, 178).

The Committee accepts that these statements define the ethical situation and considers that all clinical investigators should be familiar with their recommendations. However, because of the wide varieties of research, formal codes can provide only general guidance, and their application to specific problems must often remain a matter of opinion.

The Committee considers that it is of great importance that clinical investigation should be free to proceed without unnecessary interference and delay. Imposition of rigid or central bureaucratic controls would be likely to deter doctors from undertaking investigations, and if this were to happen the rate of growth of medical knowledge would inevitably diminish, with resultant delay in advances in medical care.

The Committee is satisfied that in the great majority of cases a very high ethical standard has been maintained in clinical investigations in this country.

The number of doctors involved in clinical investigation at the present time is large and is likely to increase, and the types of investigation are tending to become more complex. The Committee considers that it has now become necessary for a procedure to be available for the ethical guidance of clinical investigators. The provision of such guidance would not only serve to allay understandable anxiety in the public, but would be appreciated by clinical investigators themselves when faced with ethical problems.

---

[*] Members of the Committee: Sir Max Rosenheim (*chairman*), Dr. F. Avery Jones, Dr. G. M. Bull, Professor D. V. Hubble, Professor A. C. Dornhorst, Dr. J. D. N. Nabarro, Professor D. R. Laurence, Dr. J. P. P. Stock, Dr. K. Robson, and Dr. P. A. Emerson.

The Committee's conclusions and recommendations are as follows:

(1) The planning and conducting of clinical investigations demand skill, experience, and judgement. Difficult ethical problems occasionally arise and even the most experienced workers would often welcome the opinion and advice of their peers.

(2) The competent authority—for example, Board of Governors, Medical School Council, Hospital Management Committee, or equivalent body in non-medical institutions—has a responsibility to ensure that all clinical investigations carried out within its hospital or institution are ethical and conducted with the optimum technical skill and precautions for safety. This responsibility would be discharged if, in *medical institutions* where clinical investigation is carried out, it were ensured that all projects were approved by a group of doctors, including those experienced in clinical investigation. This group should satisfy itself of the ethics of all proposed investigations. In *non-medical institutions* or wherever clinical investigation—that is, any form of experiment on man—is conducted by investigators with qualifications other than medical, the supervisory group should always include at least one medically qualified person with experience in clinical investigation.

(3) The Committee deliberately refrains from formulating precise rules for supervision because the way in which this could best be organized must vary with different institutions. The variety of investigations and the importance of not discouraging the proper acquisition of knowledge that may prove useful in caring for the sick makes it necessary for each project to be considered separately.

(4) Procedures involving interference with normal function in volunteers carried out for purposes of education rather than investigation—for example, the use of drugs in student practical classes—pose special problems because of the student–teacher relationship and should be subject to the same supervision.

M. L. ROSENHEIM,
President.

COMPUTERS IN MEDICINE

Bibliography on Cannabis: a Medlars Search

The list of references below has been selected by computer at the United Kingdom Medlars Information Retrieval Service in Newcastle from a file of 500,000 references. This file was begun in 1963 by the U.S. National Library of Medicine in Washington, where the articles in over 2,000 medical journals are indexed. The index entries are then processed by computer. Outputs of the system include "Index Medicus" (published monthly; each article is listed under about three of the most important headings), and computer retrieval tapes (on which each article carries about 10 headings). The printed "Index Medicus" is available in about 200 libraries in Britain, and copies of the tapes have been made available to the U.K. Medlars service.

For a simple search, such as this one on cannabis, "Index Medicus" is quicker and cheaper, but for more complex literature problems computer searching may be economic. Inquiries should be addressed to the National Lending Library for Science and Technology, Boston Spa, Yorkshire.

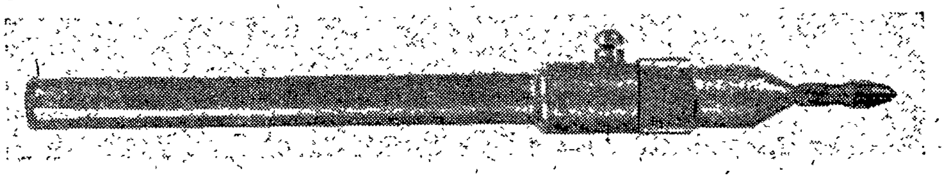
NEW APPLIANCES

Miniature Electric Drill

MR. RICHARD HARRISON, department of orthopaedic and accident surgery, North Lonsdale Hospital, Barrow-in-Furness, writes: A majority of the drills produced for orthopaedic use are easily recognized as modifications of ordinary workshop tools. As such they serve well enough for the making of large-calibre holes in, for example, the femur, but are quite unsuitable for the precise drilling of small bones which is entailed in hand surgery and maxillofacial operations. The instrument shown here was specifically designed for single-handed manipulation, and the following advantages are claimed for it: (1) Its weight and size enable it to be held in the same manner as a fountain-pen. The operator's other hand is free to manipulate the tissues being drilled. His increased sense of the direction the drill is taking facilitates to a remarkable degree such procedures as the insertion of a Kirschner wire. (2) No air-hoses or electric leads are involved. (3) The drill is sterilized as a single unit. The elimination of connexions which might become loose enhances its reliability.

The instrument is 9½ in. (25 cm.) long and has an anodized case enclosing three 1.5-v. pen-torch batteries. These are connected through a push-button switch with a motor which drives a miniature chuck through gears having a ratio of 141:1. With the batteries it weighs 5 oz. (140 g.).



The instrument is ordinarily sterilized by immersion in a 1% alcoholic solution of chlorhexidine for 15 minutes, and can with advantage be kept in a tubular plastic container filled with the same fluid. Treatment with formalin vapour, or ethylene oxide, and dry storage would also be appropriate. In the two prototype drills the batteries required renewal only after being being used for several operations, unless these followed each other in rapid succession.

The drill was designed by Mr. John Collins, of Hugh Steeper Ltd., London S.W.15, who are now undertaking its manufacture.

Letters to the Editor should not exceed 500 words.

Changed Character of Osteomyelitis

SIR,—Your leading article (29 July, p. 255) the "Changed Character of Osteomyelitis" provokes us to make certain comments in the hope of correcting a dangerous over-simplification of the problems involved.

We agree that the disease has changed from the fulminating type seen 25 years ago to a more benign type, but the local lesion may still prove disastrous to limb if not to life. In our experience the disease presents more commonly in young children and infants than in adolescents, and it is the metaphysis rather than the epiphysis which is initially involved.

Broad-spectrum antibiotics exhibited in the first 24 hours may cure the disease, but when the physical signs of local tenderness and oedema are present there is tension in the underlying bone. This calls for immediate decompression by incision and bone drilling, except in neonates, when aspiration of the abscess is often sufficient. In particular we are opposed to the observation that "when subperiosteal pus is found there is no need to drill the underlying bone." Such a finding serves to prove that the surgical intervention is already too late and that only decompression will avert years of ill-health. Delay may lead to massive sequestration, or destruction of epiphysis or joint. Without decompression pyrexia and generalized systemic disturbance may not resolve in spite of antibiotics.

The treatment of acute osteitis is based on the fact that bone cannot swell and surgical decompression is the one rational treatment to prevent ischaemic necrosis. "Better an occasional dry operation than an undrained abscess."—We are, etc.,

Thyrocalcitonin

SIR,—Your leading article on calcitonin (29 July, p. 256), accompanied as it is by the report of the Clinicopathological Conference (p. 293), is very interesting. If calcitonin is a hormone that lowers the concentration of calcium in the plasma, it will reduce the activity of the sympathetic system. When the impulse passing down the postganglionic fibre releases noradrenaline the amount released depends on the calcium concentration, and if the calcium is low very little is released.[1]

If an unusual amount of calcitonin is released, and the plasma calcium is therefore low, two symptoms may be expected owing to the ineffective sympathetic activity. The first is diarrhoea and the second is a falling blood pressure. Both these were present in the patient who was discussed at the Conference. His blood pressure was 130/80 in 1963, and was finally 95/60.

It is conceivable that the slow rise of blood pressure with age in ordinary people may be due to a declining release of calcitonin.—I am, etc.,

Oxford. J. H. BURN.

SIR,—I read your leader on thyrocalcitonin (29 July, p. 256) with interest. The references to primary sources seem occasionally arbitrary, but there is one glaring omission. No mention is made of the pioneer work and continuing important contributions of Professor D. H. Copp, who was responsible for the name "calcitonin."[1] The major part of his original work, although later modified, has proved to be correct and should be given pride of place in any review of the development of this expanding subject.—I am, etc.,

*** We regret this omission. In our issue of 5 August, p. 364, will be found a full report on the contribution Professor Copp gave on calcium homoeostasis at the Centenary Meeting of the Canadian Medical Association.—ED., *B.M.J.*

On Withholding Antibiotics

SIR,—I note from your report on the discussion concerning antibiotics at the Annual Meeting (22 July, p. 235) that it was the general practitioner's view that "antibiotics should not be withheld." This is, in a way, indicative of the present trend to misuse and plain abuse of antibiotics in general practice. Many of us seem to miss the point that the true value of antibiotics is that they have the power to reduce mortality in cases of severe infection, and that the promotion of resistant organisms by careless misuse will seriously curtail this function. Cases of fulminating pneumonia still occur, and deaths from many varieties of bacterial infection are still common. The frequency of such tragedies will increase if we disregard or minimize the risks of resistance.

The reasons for this therapeutic folly are probably several, but perhaps the major one is inadequate "antibiotic education." Whatever the answer, we may soon find that antibiotics, currently our most powerful therapeutic weapons, are becoming impotent.—I am, etc.,

St. Helens, Lancs. ALAN RUSSELL.

Clinician's Approach to Respiratory Viruses

SIR,—I should like to express my agreement with the views of Dr. Neville C. Oswald in his article "Clinician's Approach to Respiratory Viruses" (1 July, p. 35); it is certainly time for "some bridges [to] be erected between the hospitals and the virologists' strongholds." I like to think that in this area we have constructed, or are constructing, such bridges, and the clinicians do not find difficulty in having virological specimens examined. Certainly I receive a high degree of co-operation from the clinicians, and I sincerely hope this is a reciprocal arrangement. I feel the following analysis of the specimens examined supports my statement that the clinicians here can get suitable virological specimens examined without difficulty.

During the period January 1965 to June 1967 we received a total number of 11,065 specimens of which more than 80% were from hospital patients. During the 12-month period October 1965 to September 1966 we examined 2,525 serum samples and 1,616 specimens for virus isolation from hospitals. These hospital specimens were received from as many as 30 different hospitals, and the overall positive result rate was 13% and 11% respectively. These figures include specimens from the infectious disease unit, from which we examined 1,514 serum samples and 862 specimens for virus isolation; of these 18% of the serum samples were positive, and agents were isolated from 16% of the virus isolation specimens. I think these figures illustrate that, provided satisfactory specimens are sent to the laboratory, assistance can be given to the clinicians in a fair number of cases.

Clinical virology can be practised, but to be successful there must be co-operation between the clinician and the virologist. The former should appreciate that the virology department is often overworked and understaffed, that the tests are laborious and expensive, and that both quick and accurate results are only occasionally possible (accuracy must not be sacrificed for speed no matter how great the pressure of work); whereas the virologist is dependent on the clinician for collection of worthwhile specimens, without which his laboratory tests are of little value, and he must endeavour to supply results (within a reasonable time) which have some meaning to the clinician. Contact and co-operation between the clinician and the virologist should be encouraged in preparation for the day when rapid diagnostic methods and antiviral agents are available.—I am, etc.,

M. H. Hambling.

Virus Laboratory,
Public Health Laboratory,
Leeds 15.

Sir,—Dr. N. C. Oswald in his valuable article on the clinician's approach to respiratory viruses (1 July, p. 35) suggested "token laboratories under the general supervision of virologists, the day-to-day work being carried out by senior technicians."

An arrangement of this kind has proved successful in Birmingham, where such laboratories have been set up in the Children's and Dudley Road Hospitals. A well-trained technician, provided with suitable tissue cultures and media, can achieve from specimens hot from the patient an excellent rate of isolation, especially of respiratory viruses. The most skilled virologist several miles away will not do nearly so well with specimens taken by an unskilled hand and transported across several miles of heavy traffic, at some later hour when the hospital van happens to be making the journey. Sera, on the other hand, are best sent to the main laboratory for investigation. It is both tedious and expensive to set up complement fixation tests for virus infections just for a few sera.—We are, etc.,

T. H. Flewett.
East Birmingham Hospital.

K. B. Rogers.
Children's Hospital,

Ten-year Recovery from Chronic Lymphocytic Leukaemia—Twelve Years Later

Sir,—One often reads reports of patients whose illness does not conform to the ordinary run, but rarely does one hear of the subsequent fate of these patients. In 1955 I described a patient with chronic lymphocytic leukaemia who had recovered so far as to present for 10 years a completely normal picture both clinically and haematologically.[1] She died, nearly 84 years old, in November 1966. The course of her illness during her last 12 years is interesting enough to warrant reporting.

She was born in 1882. In 1943, after not feeling well for about one year, she was found to be suffering from chronic lymphocytic leukaemia with a lymphocyte count of 219,520/cu. mm. She was treated with *x* rays, her peripheral blood picture became and remained normal for 10 years, and the spleen and lymph nodes were not palpable. She had, however, recurrent respiratory infections, which responded to treatment with tetracycline. In 1961 the white cell count began slowly but steadily to rise, and continued to do so until her death in 1966. The spleen was palpable three fingerbreadths below the costal margin. Respiratory infections became more frequent and she had to be put on a maintenance dose of tetracycline in April 1965, on which she remained until her death. Respiratory infections were now less frequent and responded to ampicillin. The spleen reached the umbilicus in October 1965, and the serial blood pictures can be seen from the Table. Her final illness began in September 1966, with a lower respiratory infection mainly of the right lower zone, which at first responded to ampicillin. However, she did not recover, the lung became consolidated, the spleen had nearly reached the iliac crest, the haemoglobin fell to 38%, and she died on 7 November 1966, almost 84 years old.

The duration of the illness, if a duration of one year before diagnosis is assumed, would amount to 24 years. The longest known survival seems still to be the patient described by Marlow and Bartlett,[2] who died at 74, his leukaemia having lasted 29 years. He had always a raised white cell count and had various treatments throughout his illness. McGavran[3] described a case of 25 years' duration, also with a raised white cell count all the time. He died at 78. I have been unable to find any other cases of equally long duration in the literature.

The next point of interest is the remission of 16 years. There are several reports of long remissions in the literature, but none of them amounts to 16 years. Durant and Finkbeiner[4] report one patient with a remission of 10 years with normal clinical findings and normal blood count and bone marrow. Another of their patients had a normal blood count and bone marrow for five years, but still had "leukaemic" skin lesions. Geller[5] reports a clinical and haematological remission of nine years. Walter, Szur, and Lewis[6] report a prolonged remission with no clinical signs for more than eight years, but two marrow punctures during this time were consistent with chronic lymphocytic leukaemia in remission. Reich[7] reports a patient with normal blood count, bone marrow, and clinical findings for five years.

The ultimate fate of all these patients with remission is not known, but Wintrobe[8] seems to be right when he says that "in many instances, and perhaps always, there is a phase of long duration in which there are signs of the disease and no symptoms; very occasionally, a long period may ensue in the course of this phase when even signs are minimal or absent."

I wish to thank Dr. R. L. Turner, consultant pathologist, Bradford Royal Infirmary, for his advice and his kindness in going through the manuscript.

—I am, etc.,

Bradford 3. Max Schott.

Amoebic Pericarditis

Sir,—Slight errors are unavoidable in any general article as concise and comprehensive as that on pericarditis by Dr. K. Somers (13 May, p. 423). We feel, however, that the treatment outlined for amoebic pericarditis requires correction.

Emetine hydrochloride and dehydroemetine are extremely effective in hepatic amoebiasis, and indeed are superior to chloroquine. At present their use in amoebic pericarditis is mandatory. Chloroquine may with advantage be combined with emetine preparations, but in the dosage recommended in the article it is liable to produce vomiting. The correct dosage of chloroquine sulphate in adults would be 600 mg. of the base initially, followed by 300 mg. six hours later and then 150 mg. twice or thrice daily for 28 days.

Metronidazole has recently proved outstandingly effective in hepatic amoebiasis and may have a valuable place in the treatment of amoebic pericarditis.—We are, etc.,

S. J. Powell.

Management of Breast Cancer

Sir,—At Bristol Sir Stanford Cade (22 July, p. 227), in discussing relative values of different forms of treatment, is reported as saying that "chemotherapy was the treatment of last resort. It had never cured patients with this condition."

As initiators of systemic therapy[1] in this country we proffer some remarks on this dogmatic statement. Is it implied that there is a cure for breast cancer, or are results still to be assessed by the five-yearly, etc., yardstick? We would agree that chemotherapy, if used only as a treatment of last resort, must undoubtedly give disappointing results. It is in these circumstances that most surgeons and radiotherapists have employed such therapy. Has Sir Stanford used chemotherapy as a primary treatment for apparently early patients, and if so has he considered this facet in his judgement? Our five-year results[2] in apparently early patients, employing systemic assessment and treatment in an admittedly small series, are sufficiently encouraging to warrant continuation.

The arguments will continue anent a condition in which the deaths, using contemporary measures, have increased by 4% from 1963 to 1964,[3] but the long-repeated exercises in surgery and radiation which have hitherto shown little reward are still being pursued. The way ahead would seem to lie in improved systemic treatment for what is potentially a systemic condition even in the most apparently early patient.

Minimal controlled surgery should only be permissible when a satisfactory systemic picture is present or obtained, and should certainly be delayed in the advanced patient. In the meantime, to catch the patient in apparent (with a negative systemic assessment) true Stage 1 should be our aim, since the results of treatment by any method are relatively good.

We note that early detection at well-women clinics and self examination was not discussed at the symposium—the early detection of what is usually a symptomless condition is surely a prime necessity.—We are, etc.,

Wassermann Reaction and Vaccination

SIR,—The percentage of the normal population in which positive Wassermann reactions may be detected depends on the sensitivity of the lipoidal antigen used. This explains Lynch's[1] high figure of 27% acute positive biologically false-positive reactions following vaccination, cited in your leading article (13 May, p. 394). This is borne out by a detailed examination of Lynch's results:

Type of Antigen Used	Type of Response to Vaccination	
	Primary	Accelerated
Very sensitive lipoidal antigen Hinton test	35/96 positive*	7/114 positive*
V.D.R.L. test (quantitative)	4/97 positive*	1/115 positive

* Doubtful results excluded.

Similar results have been suggested by Salo *et al.*,[2] who gave an overall figure of 6.6% acute positive biologically false-positive reactions using the V.D.R.L. antigen, following vaccination.

Thus the commonly used V.D.R.L. test yields a result of nearer 6% positive acute biologically false-positive reactions rather than 27%, so presenting far less of a problem than represented. Although almost all subjects (with the exception of those, in theory only, without any reagins) will produce a rise in reagin titre, only 6% will have a sufficient rise to be detected by the less sensitive V.D.R.L. test.

It would be of great advantage if the lipoidal antigens were not only standardized with respect to other laboratories but also to "biological phenomena."—I am, etc.,

Diet and Diverticulitis

SIR,—My views on the importance of diet in the causation of diverticulosis coli have been misrepresented in your correspondence columns by Dr. E. H. Goulston (6 May, p. 378), when he commented on a letter by Drs. T. L. Cleave and G. D. Campbell (2 July, 1966, p. 50).

They pointed out that African natives living on a tribal diet do not develop diverticulosis, but they do so when they become urbanized and change to a Westernized diet. Also, thirty years ago their coloured cousins in the U.S.A. were less affected by the disease than their white compatriots, whereas nowadays both racial groups are equally prone to develop diverticula. Concurrently the amount of maize eaten in America has decreased dramatically. Drs. Cleave and Campbell blame the increased use of refined carbohydrates in the form of white flour and sugar in our so-called civilized diet for these changes, and have submitted evidence for this conclusion elsewhere.[1]

Dr. Goulston dismissed their theory, saying that, "The time-honoured label of colonic stasis and diet as regards aetiology (of diverticulosis) is wearing thin, especially when one reads the studies by N. S. Painter *et al.* . . ." This implies that I disagree with Drs. Cleave and Campbell and that I consider that our diet does not cause diverticulosis. Nothing could be further from the truth.

My studies on the pressures in the human colon in health and diverticulosis did not reveal the aetiology of the disease but its pathogenesis. The pulsion force that drives the colonic mucosa through the muscle coat is generated by segmentation of the colon, which can produce high localized intracolonic pressures. Segmentation occurs spontaneously or can be caused by emotion, mechanical stimuli, or by certain drugs, of which morphine is one. I have suggested that segmentation, and hence high intracolonic pressures, may be caused by our diet or by substances that we inhale. I have argued that a colon of small diameter can segment more readily than a colon that has a large lumen, and hence that a narrow colon is more prone to develop diverticula.[2-4] This would explain why rats, which have a narrow colon, owing to being fed on a low residue diet, develop diverticula,[5] while Africans, who eat a high residue diet and have a wide colon, remain free from the disease. It is my belief that a high residue diet may be contraindicated in the treatment of the established disease.

It would be ridiculous to attribute the rapid increase in the incidence of diverticulosis in Western society to a genetic change, so, if the human body has not changed, the disease must be caused by external factors affecting the body. Drs. Cleave and Campbell have presented evidence that our "civilized" diet is responsible not only for diverticulosis but also for other diseases. Only when the factors in our diet that cause increased segmentation and pressure production have been identified will both the pathogenesis and the aetiology of diverticulosis be known. Meanwhile the simple theory advanced by Drs. Cleave and Campbell—namely, that our diet is abnormal and responsible for many of the ills that affect civilized man—deserves consideration and immediate investigation.—I am, etc.,

Treatment of Radiation Sickness

SIR,—The communication on this subject by Drs. H. Mattie, E. W. Emery, and I. D. Hill, and Professor D. R. Laurence (22 July, p. 215) does little to clarify the longstanding confusion about the value of drugs in the treatment of radiation sickness. They carried out in 82 patients a double-blind trial comparing the effect of 3 mg. pyridoxine hydrochloride daily with 150 mg. daily, and established no significant difference. No attempt was made to demonstrate that pyridoxine administration at *any* dose level is more effective than a placebo, and in fact they quote two reported controlled trials as showing no difference between the two.[1 2]

Their series of cases is of course too small to provide significant information on this problem when analysed according to criteria emphasized by me 10 years ago[3]:

(*a*) Radiation sickness comprises a complex of symptoms, of which each symptom must be considered separately for response. Vomiting is the easiest of all to control, nausea rather less so, while anorexia and lassitude are the most resistant to treatment.

(*b*) The degree of relief of each symptom, partial or complete, must be specified. Whereas abolition of vomiting can be measured quantitatively, the complete abolition of lassitude and anorexia is in my experience almost impossible for a patient to admit.

(*c*) In view of the variation of degree of radiation sickness with the site of irradiation, size of field, and daily dose, drugs are best compared on the basis of their efficacy in relation to one specific technique. Postoperative breast irradiation is well suited to this purpose.[2 4]

(*d*) Placebo tablets give a surprisingly high proportion of relief of symptoms. They relieve vomiting in over 50% of cases as a whole, although the proportion relieved is much smaller when the abdomen or pelvis is being irradiated. Thus the proportion of patients receiving treatment to this area must be equated to compare any two series.[5]

I have published an analysis of over 1,000 controlled drug trials in radiation sickness based upon these criteria.[5] Included were 201 patients receiving 40 mg. daily of pyridoxine hydrochloride and 60 patients receiving a placebo (30 mg. lactose daily). The patients were randomly selected on a calendar basis, although no attempt was made to make up tablets in identical form. When the material was subdivided according to the criteria specified above pyridoxine was found superior to the placebo in the following respects: completeness of relief achieved, relief of anorexia and lassitude, and relief of symptoms following abdominal or pelvic irradiation. All these are the most resistant to relief.

Only by the detailed analysis of such criteria in large series of cases will the value of drugs in radiation sickness be clarified.—I am, etc.,

A Case for Cannabis?

SIR,—In your leading article "A Case for Cannabis?" (29 July, p. 258) you state categorically "Cannabis has no known therapeutic value . . .," and give as the reference to this *Brit. med. J.*, 1964, **2**, 1348. Perhaps your leader writer overlooked *Guy's Hospital Reports*, 1954, **103**, 330.—I am, etc.,

DAVID STAFFORD-CLARK.

York Clinic,
London S.E.1.

⁂Dr. Stafford-Clark rightly draws attention to a case reported by himself and Dr. E. J. Rolls in which alcoholic tincture of cannabis was used in the treatment of a depersonalization syndrome which immediately followed labour. The syndrome had failed to respond to other therapy, and after treatment using cannabis the patient recovered rapidly and completely.

The leading article made the point that little research had been done on the pharmacological activity of cannabis in man, possibly because of its lack of "known therapeutic value." The most recent edition of "Martindale"[1] states, "Cannabis was formerly employed in mania and nervous disorders as a cerebral sedative or narcotic and it has occasionally been used for the relief of migraine and of headache due to hypertension. It is now rarely used as a therapeutic agent. Its action is very unreliable. Different samples of cannabis may vary greatly in potency." At p. 430 of this issue we print a list of publications mentioning cannabis abstracted by Medlars from 2,000 journals in the world literature for the period from 1963–7. Very few of these papers are clinical.—ED., *B.M.J.*

REFERENCE

[1] *Extra Pharmacopoeia*, 1967, 25th edition. London.

SIR,—I would like to commend the good sense of your leading article under the above heading (29 July, p. 258). The subject of drug addiction is part of the bigger one of the misuse of drugs of all kinds. This is one of the largest diseases of modern life; partly iatrogenic and much more a social one. The generality of drugs are overprescribed and overdemanded. They are not treated with respect; adults are careless, children are poisoned, character is eroded, accidents are facilitated, money is wasted, and political control is nonsensical.

As to cannabis, we should remember that it has an evil reputation going back many centuries. Intoxication with "hashish" led to murder, thus the origin of the word "assassin."

Scientific study of the drug is no doubt desirable, but the whole nation needs to look into its own actions and seek for the creative development of beauty, compassion, and indeed hard work for its future (*poiesy*).—I am, etc.,

Exeter. NORMAN CAPENER.

Disinfectants and Plastic Mop Heads

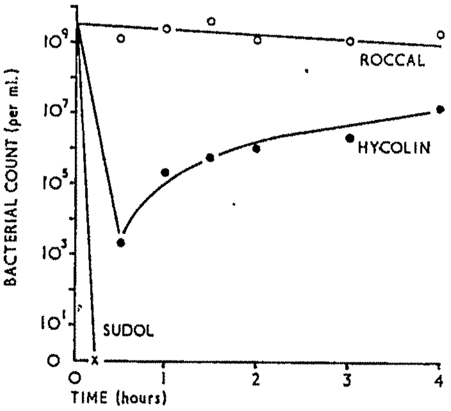
SIR,—There is very little agreement about the best disinfectant to use for hospital cleaning procedures, and cleaning equipment is made of a variety of materials. It is known that some varieties of plastic will interfere with the action of disinfectants, but in view of the lack of advertisement of this problem we would like to report the recent findings in our renal transplantation unit.

The unit consists of single-bedded rooms, the floors of which are individually cleaned each day with a plastic mop which is stored after use in a disinfectant solution in each room. The mop head is made of polyurethane foam and can be autoclaved.

In October 1966 routine culture of a mop head and of the disinfectant solution showed a heavy growth of *Pseudomonas aeruginosa* which was resistant to Roccal (0.05%) the disinfectant in use at that time. The disinfectant was therefore changed to Hycolin (1%), to which the organism was sensitive, and new mop heads were issued. Subsequent culture of the mop heads, however, again grew large numbers of *Pseudomonas aeruginosa*, and since the material of which the mop head was made seemed to be interfering with the action of the disinfectant the compatibility of several disinfectant solutions with the plastic mop head was examined.

The effect of Hycolin, Roccal, and Sudol was tested on four pathogenic bacteria isolated from infections in renal transplant patients. The organisms were *Pseudomonas aeruginosa* (pyocine type 10), *Escherichia coli 0111*, *Staphylococcus aureus* (phage group III), and *Candida albicans*, which were grown overnight in nutrient broth; the following morning the disinfectant solutions were added to give a final concentration of Hycolin 1%, Roccal 0.05%, and Sudol 2.5%. Two cultures were used, one containing the disinfectant solution alone and the second containing in addition a sterilized cube of plastic from the mop head. The bottles were placed on a mixer and quantitative bacterial counts were carried out at 30-minute intervals.

All organisms were killed by the three disinfectants alone in 15 minutes, with the exception of *Pseudomonas aeruginosa*, which was resistant to Roccal. When the plastic was present the *Staphylococcus aureus* and *Candida albicans* were still sensitive to the disinfectant solutions, but *Escherichia coli* was not killed in Roccal and *Pseudomonas aeruginosa* survived in Hycolin. The effects of the three disinfectants on *Pseudomonas aeruginosa* is shown in the Figure; it was found that Sudol was still effective within 15 minutes, but Hycolin, although reducing the bacterial count initially, did not completely eliminate the organism and after 30 minutes sufficient sorption of the disinfectant on to the plastic had occurred to allow the organisms to grow again. A similar effect was seen with *Escherichia coli* and Roccal. It was possible by increasing the working concentration of Hycolin to 5% to eliminate this effect, but in this high concentration toxic effects and hypersensitivity reactions are more likely to occur, and the risks to cleaning staff are increased.



As a result of these experiments it was decided to use Sudol as the disinfectant in ward cleaning procedures and to continue using the same plastic mop.

The purpose of this report is not to advise on the use of a particular disinfectant or mop head but to suggest that care must be taken in the choice of a particular combination. Incompatibility between disinfectant and plastic can be detected only by bacteriological examination, and constant supervision should be carried out.—We are, etc.,

Potentiation of Anticoagulants

SIR,—We read with interest the letter of Drs. B. I. Hoffbrand and D. A. Kininmonth (24 June, p. 838) commenting on the potentiating effect of phenylbutazone on coumarin anticoagulants. We should like to report a further example.

A man aged 62 had been treated with warfarin for eight months following a myocardial infarct. His anticoagulant control had been good, and on a dose of 10 mg. daily of warfarin his prothrombin time was between 24 and 28 seconds with a control of 11 to 12 seconds. He attended hospital on 20 June 1967 complaining of severe right sciatic pain and was admitted to the ward.

The previous day, in addition to the usual dose of warfarin, he had taken 400 mg. of phenylbutazone, and on the morning of admission 100 mg. On 21 June his prothrombin time was found to be greater than 60 seconds with a control of 12 seconds, and without further warfarin his prothrombin time was as follows:

22 June	43 seconds (control 12 seconds)
23 June	52 seconds (control 12 seconds)
24 June	24 seconds (control 12 seconds)

Liver function tests, including the bromsulphalein test, were normal.

There seems to be no doubt that the effect of warfarin was potentiated by phenylbutazone in this patient, and it is interesting that the total dose taken was only 500 mg.—We are, etc.,

Safer Dental Anaesthesia

SIR,—I am both puzzled and perturbed at the tendency of some of your leading articles to be written with such complete lack of balance. The most obvious of these was " Anaesthesia for Dental Extractions " (25 February, p. 447), which seems to be expressed entirely from the academic point of view. To take but one example, there is the categorical statement, " Undoubtedly the safest method of operating in the oral cavity is under endotracheal anaesthesia. . . ." No exceptions are even suggested, though it is granted that the numbers of patients are too great for its universal application. If strictly true, how does one account for the fact that throughout some 40 years of close association with both dental surgeons and anaesthetists I cannot think of one who, if confronted with the personal problem of the extraction of a septic tooth or teeth in the anterior part of the mouth, would request for himself the " safest method," knowing as he does its possible attendant discomforts.

Similarly, in your article " Safer Dental Anaesthesia " (8 July, p. 64) there is quoted the paragraph[1] that the " administration of general anaesthesia and the performance of dental surgery require the undivided attention of anaesthetist and operator respectively and . . . cannot be combined without risk." You go on to say, " This authoritative statement will surely receive general assent." The word " authoritative " seems to be added for good measure, but as there is nowhere any evidence of any kind to support this statement (and this over the analysis of over 10,000,000 cases) it would have been fairer to leave it out.

What has been omitted from the article is the growing demand on the part of the public for painless conservative dental treatment by means of intravenous medication. The conception and application of this differs so greatly from the general anaesthesia and the performance of dental surgery that, as mentioned in the third recommendation of the Report,[1] it has become a separate entity and is deserving of special study by anyone interested in relieving the patient of mental distress as well as physical pain.

Howe and Hovell[2] make the point, " The recommendations detailed in the report may or may not be sound, but what is certain is that they are based not on facts but on expressions of opinion."

It would indeed seem that some of the pundits who range themselves so strongly against an extension of methods whereby the patient experiences less discomfort and pain during conservative dental procedures do so from a variety of reasons, some of them academic more than practical, and so fall into the " Fruits of Error and False Assumption " as so adequately described by Lord Cohen[3] and also from emotional and illogical reasons similar to those historically recalled by the furore about anaesthesia in childbirth, subsequently upon the introduction of local anaesthesia for dental conservation, and now by the extended use of intermittent methohexitone or the Jorgensen technique.—I am, etc.,

SIR,—Without going into the main deficiencies of the Government Report on Dental Anaesthesia,[1] which are almost all connected with the expression of personal opinion without acceptable supporting evidence, your leading article on the subject seems to be satisfied with a low order of conciseness and clarity to mete out congratulation (8 July, p. 64).

It has been agreed by the British Dental Association that the subject of training is of greatest importance. The B.D.A. are especially keen on retaining the rights of dentists to give anaesthetics.

Such is the conciseness and clarity of the report that the Council of the B.D.A. issued a paper[2] agreeing with this section. This is tantamount to saying that dental students should receive no practical training in anaesthetics and that dental graduates could not receive any postgraduate training which would enable them to provide a service.

The first point is dealt with in paragraph 31 of the report, but to check the second one must study paragraphs 33, 34, 35, and the reasonable potential capacity of six-month postgraduate courses, which would be unlikely to exceed 50 places a year in the foreseeable future, whereas 700 would be needed.

Little in the report seems to be based on practical experience. The authors claim to examine the criteria for safety " in some detail," yet do not mention the importance of protection of the airway, of effective packing, and of the simple measures one should adopt to prevent, rather than having to treat, emergencies.—I am, etc.,

S. L. DRUMMOND-JACKSON.

Aversion Therapy of Homosexuals

SIR,—In your issue of 3 June (p. 594) you published a report on the treatment of homosexuality (I did not know it was a disease). The authors are to be congratulated on their honest and sincere report which prompts me to a similar comment.

From 43 persons—allow me not to call them patients, although the " treatment " inflicted upon them entitles them to it—18 appeared for treatment in connexion with a court appearance. Twenty-five had some personality disorder associated with their homosexuality—court appearance or other people's attitude to them. Four presented with symptoms other than their homosexuality. Only seven preferred partners under 16.

It is obvious that, excluding the last two categories, at least 32 persons have been subjected to a treatment of their homosexuality because society disliked their sexual practices. After treatment half of the 43 were converted to " active " heterosexuality. In short, because of these persons' unconventional sexual practices they have been conditioned to conventional ones, so much so that it looks as though fornication has become an end in itself.

If this treatment gives such satisfactory results is there any reason why enthusiasts should not extend it to conditions such as promiscuity or adultery ? And if we extend it to people with less conventional views than ourselves in general we will be in 1984. At a time when lay people begin to have enlightened views on sex and sexual behaviour is it too much to expect the profession at least to follow suit if it is unable to be in the forefront ?—I am, etc.,

Bamford, Rochdale. B. KALCEV.

Results of Augmented Histamine Tests

SIR,—It is scarcely surprising that Mr. R. J. Abernethy and others (22 July, p. 205) should find highly significant correlations between the post-histamine acid output in the whole hour,[1] mid-half-hour,[2] and peak half-hour.[3] In a comparable study[4] " a highly significant correlation was found between the values of the samples 0–40 and 20–60 minutes and the MAO [maximal acid output]," but Carneiro de Moura and Pinto Correia went on to comment on their own highly significant correlations : " In fact, these correlations are spurious because the same component (0–40 or 20–60) appears in both abscissa and ordinate."—I am, etc.,

Folate Deficiency in the Elderly

SIR,—The last statement in Dr. J. D. B. Andrews's letter (22 July, p. 244)—namely, " However, as serum folic levels probably do not accurately reflect tissue state, the diagnosis or exclusion of folate deficiency on serum folate levels alone appears unjustified," demands comment as it seems to carry the air of dismissing the value of serum folate estimations. Dr. Andrews's supposition could be correct, but it would help to hear more supporting facts as a case to the contrary can be made as follows.

For the purposes of this discussion I take the word " accurate " in medicine to mean accurate enough to be of practical value. Professor Leevy *et al.*[1] showed that serum folate levels reflect liver tissue levels surprisingly accurately. Chanarin *et al.*[2] demonstrated similar findings.

It may be that serum folate levels do not reflect tissue levels in tissues other than the liver. If this is so, has Dr. Andrews any facts to support this ? There are abundant publications, too well known to require reference, that patients with low serum folate levels and changes believed to be secondary to folic acid deficiency respond when given folic acid. This is strong supporting evidence that serum folate levels reflect tissue levels accurately enough for practical purposes. The folate level in the central nervous system[3] is three times that of serum and falls when the serum folate falls. This also suggests that serum folate levels can give a helpful reflection of folate levels elsewhere in the body.

The serum estimation of any substance—e.g., potassium—requires sensible interpretation. Estimations used in this way have served us well for years. The day when an easy estimation of tissue substances can be achieved is probably many years off. Meanwhile it would be unwise to reject such guides as are available. We must do the best with those we have ; which probably are accurate enough for practical purposes.—I am, etc.,

Dietetic Treatment of Phenylketonuria

SIR,—I read with interest the recent follow-up study of the 57 children with phenylketonuria by Dr. Barbara Clayton and others (15 July, p. 133). The age when treatment is started and the occurrence of epilepsy are certainly two factors affecting a satisfactory outcome to treatment, but the following case may be of interest.

A male infant had a normal birth and at 8 weeks gave a negative reaction to a routine Phenistix test. The occurrence of frequent (4-5 a day) "infantile spasms" caused him to be admitted to the Royal Salop Infirmary under Dr. J. C. Macaulay at 8 months, when he was found to be suffering from phenylketonuria, and he was subsequently put on to a low phenylalanine diet.

In retrospect many of the recognized milestones were delayed. He did not sit on his own until 11 months, he did not start to walk until 18 months, and when I first saw him at the age of 3½ years, although he appeared bright and had a good vocabulary, he was still having a little difficulty with urinary continence during the day. Both parents are intelligent and I would assess the "quality of treatment" and maternal care as good.

At the age of 4½ years the lad was tested on the Stanford Binet scale and an I.Q. of 109% was obtained. He was recently admitted to the local school and at the end of his first term the head-teacher commented that he appeared a bright lad but easily distracted from sustained work, though beginning to settle well. This had been noted during the I.Q. assessment.

It is too early to give any firm prognosis regarding his future at school, but this is a lad who, because of late detection and the occurrence of epilepsy, might not have been expected to have done as well as he has.

This case seems to be worth reporting, as the follow-up study contained only one child (Case No. 20) detected after the age of 6 months and showing evidence of epilepsy who has been placed within the normal educational system, and his last I.Q. fell within the educationally subnormal range.

The presence of "fits" in a child with phenylketonuria would seem to make a favourable outcome unlikely but not an indication for withholding treatment.—I am, etc.,

BRIAN E. DEERE.

County Health Offices,
Newtown, Montgomeryshire.

Cardiac Resuscitation

SIR,—If the problem of who should be resuscitated is a difficult one for nurses in hospital how much more difficult for the first-aider in the factory or in the street. He has not the advantage of seeing seriously ill patients daily to help him in assessing the condition of a collapsed casualty, nor does he usually know of the past and present medical history, which the nurse would have been told on the patient's admission. Why then did the first-aid organizations of St. John, St. Andrew, and the British Red Cross[1] choose to ignore the carefully thought out conclusion of the Symposium on Resuscitation in 1961[2] that cardiac resuscitation should be taught only to "doctors, nurses, and recognized life-savers" ?

There is already too much knowledge to be absorbed in the 16 hours' instruction recommended for the first-aid course, and the result is obvious to anyone regularly involved in examining candidates for the St. John certificate. While the technique of cardiac compression is easily learnt and remembered, the indications for it are often not clearly understood, and one feels that cardiac arrest would seldom be diagnosed correctly. Presumably this would not matter if the procedure was entirely safe, but complications such as fractured ribs, haemothorax, haemopericardium, and visceral damage have been reported with relevantly experienced resuscitators.[3,4] These are not likely to improve the chances of recovery of a severe cardiac infarction or oligaemic shock, and I would suggest that unless far more time and care are spent in teaching resuscitation it is likely to do more harm than good.—I am, etc.,

Dopa and Parkinsonism

SIR,—Assuming that the identification of tyramine in excess in the urine of patients with Parkinsonism[1] and the improvement in such patients on feeding dopa[2] can be confirmed, these findings are in keeping with the postulated defect in hydroxylation in this syndrome. Normally the amino-acid phenylalanine is hydroxylated to tyrosine, which is then hydroxylated to dihydroxyphenylalanine (dopa), this finally being decarboxylated to yield dopamine. If a defect in tyrosine hydroxylation exists in Parkinsonism then tyrosine would be decarboxylated to yield tyramine, thus explaining Boulton and colleagues' findings.

Feeding of dopa would result in a return to normal levels of dopamine in the substantia nigra and corpus striatum, thus ameliorating the symptoms. That the symptoms of Parkinsonism may not be solely due to depleted stores of dopamine, however, is suggested by the finding that feeding of phenylalanine aggravated them. This would tend to suggest that an abnormal metabolite of tyrosine is also involved in producing the clinical features.

The occurrence of athetoid movements on feeding dopa is extremely interesting, but it would be rash to speculate on the significance of this.—I am, etc.,

Infectivity of Scabies

SIR,—While I am in complete agreement with the views of Dr. Lionel J. Bacon (6 May, p. 373) and Professor J. T. Ingram (20 May, p. 506), it is with some concern that I find the myth of transfer of this infestation by clothing and bedclothes is still being perpetuated. My experience of close contact between cases of scabies and venereal disease in a ship in 1942-3 without a single case of cross infection in spite of the fact that bedding was often shared has been confirmed by my experience since that time.

I was responsible for the care of skin and venereal cases in a ship between September 1941 and October 1943. The crew of 1,500 adult males formed a closed community. During the two-year period visits were made to ports in the temperate and torrid zones. Men were allowed leave either for short periods of four hours or overnight for 12 hours. Their contact with a source of infection was, therefore, either for four hours or for 12 hours. The incidence of scabies and venereal diseases was fairly high. For one six-month period in 1943 the figures were: scabies 106, gonorrhoea 18, urethritis 11, balanitis 10, syphilis 4, soft sore 2 (unfortunately figures for the whole period are not now immediately available to me).

Cases of scabies and venereal disease once diagnosed were segregated in a common mess in the ship and no attempt was made to separate them. They carried out their normal duties. They slept in hammocks and a man coming off duty frequently turned in in the hammock of the man going on duty. No attempt at disinfestation of bedding or clothing was made or possible. During the two-year period no case of cross-infection was found. It was noted that scabies was not contacted when shore leave was limited to four hours, but only when overnight 12-hour leave was given. This was not found with the venereal diseases.

Therefore I am convinced that casual contact cannot lead to transfer of the infestation but that intimate contact with the infected host for some hours is necessary.

Unfortunately, I cannot entirely agree with the views expressed by Dr. J. O'D. Alexander

(17 June, p. 766). In my opinion, treating a case of itching as scabies on suspicion but without confirmation is unwise. The recent interest in scabies has led to a marked increase in the number of patients referred to this hospital for diagnosis following empirical treatment with benzyl benzoate. Where suspicion has not been well founded and the itching has been due to some other cause, time has been lost in arriving at a diagnosis and the symptom, itching, for which treatment was given, has been worsened. Itching is not synonymous with scabies and scabetic infestation can be found without itching. The acarus is the cause, can be seen, and can be killed.—I am, etc.,

Victoria Infirmary,
Glasgow S.2.
R. W. CARSLAW.

Compulsory Treatment of Addicts

SIR,—I am sorry that Dr. H. D. Beckett (24 June, p. 841) has not had an opportunity of referring to my paper on drugs causing dependence[1] where I originally said that "a kindly compulsion will be the first step in treatment" and later gave it as my opinion that "we must separate the addicted 'pusher' from the non-addicted 'pusher.' The addicted pedlar needs treatment, not punishment. But the non-addicted 'pusher' or pedlar is a criminal; he is the murderer of the soul and the mind."

These are the persons who, in Ohio, have been imprisoned for 20–40 years and it is in Ohio that drug addiction has been almost completely eliminated from the State.

Can Dr. Beckett recommend any better method of controlling drug addiction?—I am, etc.,

Regurgitation during Induction

SIR,—Dr. L. Rendell-Baker (20 May, p. 507) questions the safety of "crash intubation" of the trachea under anaesthesia in the presence of a full stomach compared with the safety of awake intubation in similar circumstances.

There is little doubt that of the many different techniques of "crash intubation" that have been described none can be regarded as completely safe. However, it is probable that much of the danger of such intubation could be eliminated if in all cases where a full stomach is suspected three basic safety procedures were undertaken prior to induction of anaesthesia. Firstly, an adequate oesophageal tube (absolute minimum size—10 E.G./18 F..G) is passed into the stomach, and, immediately preceding induction, the contents of the stomach evacuated as far as is possible. Secondly, the patient is placed on a non-slip mattress on a properly tilting theatre table. Thirdly, efficient suction apparatus with wide-bore tubing (without constrictions) is in action, the sucker end being held by a nurse at the head of the patient.

It would seem that in many centres there is a failure on the part of anaesthetists to carry out the above safety procedures, with the result that death during intubation due to the inhalation of stomach contents still remains a not uncommon occurrence. This failure stems no doubt from a mistaken faith in the absolute safety of some one particular technique of intubation.

In seeking to reduce the mortality due to inhalation of stomach contents there is, however, a fundamental question to be considered, a question that has yet to be fully answered. In anaesthesia in the presence of a full stomach under what circumstances does the act of intubation itself occasion more hazard to the patient than is entailed in carrying out the operation with the patient not intubated?—I am, etc.,

Middlesbrough,
Yorks.
D. DENISON DAVIES.

Mortality of the Ambulance Ride

SIR,—Mr. D. Lamont refers in his letter (6 May, p. 374) to the "mortality of the ambulance ride." This merits consideration in its own right.

One of us accompanied a road-accident case with multiple injuries during his transfer by ambulance to an intensive care unit at another hospital, the patient while in our hospital having been resuscitated twice from cardiac arrest and later from secondary shock. Within one mile the jogging up and down of the ambulance ride caused a recurrence of shock despite continued blood transfusion and intermittent positive-negative pressure respiration with a Manley respirator. The blood pressure dropped from 110 to 90 mm. Hg systolic, and the skin became cold. This state persisted throughout the journey, which took 47 minutes, although the roads were good, the speed limited to 20–30 m.p.h. (32–48 km.p.h.), and stopping and starting eliminated by a police escort. The patient's condition improved soon after arrival in the intensive care unit, where he recovered consciousness, but he developed renal failure from which—together with damage to brain and spinal cord—he died five days later. It is impossible to exonerate the ambulance ride from being an important secondary factor contributing to his death.

The jogging of the ambulance ride caused the patient's body to bounce up and down through a range of about 6 in. (15 cm.). It was clearly due to the design of the ambulance suspension, which has not kept pace with that of private cars. As a shock-producing factor it would have been exaggerated by bad road surfaces; by the centrifugal force of rapid cornering; and by any period of time spent ascending a hill, during which the patient's body would have been subjected to the anti-Trendelenburg position and its well-known ill-effects on the supply of blood to the brain, which would in many cases be sufficient to cause respiratory arrest and death.

It would seem to be possible, from our experience as motorists, to reduce these factors by paying some overdue attention to the design of the suspension. The ambulances based on the Citroën Safari, as used on French and Spanish roads, have an obvious claim to investigation because of their well-known merits on bad as well as good roads. In addition, some means of keeping the body horizontal is essential.

Until the ambulance ride ceases to be an important factor in the causation of essentially avoidable death, no acute hospital should be closed if a longer ambulance journey is entailed for seriously ill or injured patients. The distance between intensive care units must also remain a critical factor. It is clear that any serious attempt to prevent essentially avoidable death must also involve on-the-spot skilled resuscitation of the gravely injured patient before transfer to hospital, as suggested by Mr. Lamont.—We are, etc.,

Oculogyric Crises Due to Phenothiazines

SIR,—I was interested to read Dr. J. R. Harries's letter (22 July, p. 241) in which he reported three of these cases, as a similar type of case was seen at Queen Mary's Hospital, Roehampton, last year, in which the phenothiazine drug was thiethylperazine (Torecan).

In June 1966 a 14-year-old boy was referred to the Department of Oral Surgery at Queen Mary's Hospital, Roehampton, with a provisional diagnosis of recurrent dislocation of the temporomandibular joints. He had started taking thiethylperazine 10 mg. and tablets of tetracycline the previous morning, which had been prescribed for a gastrointestinal upset. After two tablets of each he began to have spasms of his facial and tongue muscles which lasted less than a minute and occurred several times an hour. He continued with the tablets, and when he was seen at Queen Mary's Hospital he had taken about six tablets of thiethylperazine and an equal number of tetracycline tablets. He and his parents were in some doubt as to exactly how many of each tablet he had taken.

By this time the "spasms" were almost continuous. Every few minutes his mouth opened widely and he would protrude his tongue. He had no abnormal eye movements. He was apparently distressed by these attacks and would attempt to close his mouth by pushing against his mandible with both hands. He was admitted to hospital, given no more thiethylperazine or tetracycline, and sedated with phenobarbitone. The muscle spasms stopped within an hour, but oddly enough returned for the duration of his parents' visit later that evening.

The following day he had no attacks and the day after that he was discharged home. As far as is known, he has had no similar attacks since then.

I am grateful to Mr. Rowe, consultant oral surgeon, for permission to report this case.

—I am, etc.,

Westminster Hospital,
London S.W.1.
JAMES McIVOR.

SIR,—I feel that my colleagues might be interested to hear of the dramatic side-effects I have recently found in a patient on a minute dose of trifluoperazine (Stelazine). The symptoms were those of acute Parkinsonism, affecting the jaw, tongue, and eye muscles. The patient had had only three spansules of trifluoperazine 2 mg. b.d. for two days. On the evening of the second day she developed a tremor of the hands and inability to close her mouth, symptoms which gave every appearance of being hysterical, but gradually reached the most painful state of spasm.

I have seen these symptoms on two previous occasions, once with perphenazine (Fentazin), 1 mg. t.d.s., and once with prochlorperazine (Stemetil) 5 mg. t.d.s., side effects occurring dramatically on the second day in all three cases.

I injected pethidine 100 mg. i.m. and quickly drove to the surgery to get some benzhexol (Artane). By the time I returned the spasm had been relaxed by the pethidine, but there was still a degree of oculogyric crisis which improved on orphenadrine hydrochloride (Disipal) t.d.s. over the next 24 hours. As this was a fit young woman with no background of hysteria, I feel it is worth drawing attention to these occasional dramatic side effects.

During six years in a psychiatric unit where patients received doses of over 100 mg. of potent tranquillizers, we never saw a case of such severity. Parkinsonism seemed to manifest itself in pill-rolling movements, excess salivation, and some rigidity of the facies.

These three cases which have occurred in our practice over the past five years have all shown that unless the general practitioner is aware of this problem the patient is treated as a hysteric.—I am, etc.,

Bracknell, Berks. M. R. MEDHURST.

Cervical Cytology

SIR,—Dr. R. D. Last's experience of cervical cancer below the age of 35 years (29 July, p. 311) is by no means isolated.

In this department we accept smears from all women aged 25 years and over. In the first six months of this year we examined approximately 1,000 smears from women aged 25–34 years, nearly all from the antenatal and gynaecology clinics of this group. Among them we found five positive smears confirmed by biopsy, and three more still awaiting confirmation. Assuming that at least two of the latter are proved positive (we have had one false positive in 9,000 smears), we have found at least seven positive smears in 1,000 women, a rate which compares very favourably with the national average.

We have also seen 15 biopsies from cases of clinically invasive cervical cancer in the last three years. Of these, one was aged 35 years, two 34 years, and one 24 years.

These figures surely show the only excuse for discouraging smears from women under 35 years is a lack of trained staff to examine them. This difficulty varies from place to place; and if the local laboratory can take on the work, then the Ministry should be prepared to pay for it.—I am, etc.,

J. A. U. MORGAN.

Department of Pathology,
Hackney Hospital,
London E.9.

SIR,—I read with dismay that the Chairman of Council received the report on the development of the cervical cytology service with satisfaction (8 July, *Supplement*, p. 15). It seems extraordinary to be satisfied with a total number of tests in Great Britain scarcely above the number carried out in British Columbia with its tiny population.

I would like to know who proposed that a test every five years offered safety; that there is magic in the age 35, so that a doctor taking a test at or over this age receives a fee, whereas at 34, 24, or even 18 no fee is payable. Whatever the statistical purist may think the individual woman screened every year or (second best) every two years is protected from cervical cancer. If this is accepted then nothing short of a screening service available for all volunteers should be accepted.

I hope Dr. J. C. Cameron (same report) will keep up the pressure on the Ministry and on regional hospital boards.—I am, etc.,

H. C. MCLAREN.

Queen Elizabeth Hospital,
Birmingham 15.

Another Hardship of Hospital Junior Staff

SIR,—May I, through your columns, attempt to point out some of the hardships caused by hospital appointments being made so soon before the vacancy actually falls?

Let me say at once that I do see the disadvantages of appointing hospital junior staff too far in advance. But against this, surely the difficulties that the unfortunate hospital junior staff inevitably suffer as a result of an "eleventh hour" appointment must be weighed.

Their applications are considered perhaps five to six weeks (or even more) prior to the vacancy. But the actual appointments are often made only about three weeks in advance.

The consequences are obvious: there is very little time to pack up one's belongings, find new accommodation and move (possibly with a wife and family). For a minority too, a move must entail finding a new kindergarten. If one has just vacated a flat, one cannot give the one month's notice as is so often stipulated by landladies, the gas and electricity boards, so that one may be asked to pay one or two weeks' "unnecessary" rent.

If one is moving to a town where difficulties in finding accommodation are anticipated —such as Oxbridge (admittedly perhaps an unfair example, but nevertheless one which will illustrate my point)—is it right that appointments for jobs commencing say on 1 October are not made until the first or second week of September?

No doubt these points have been raised before, but I do regret that the consultants en masse are not more sympathetic to them. —I am, etc.,

Plymouth. MICHAEL COSGROVE.

Without Prejudice

SIR,—May I ask you to convey to Pertinax at this time my personal thanks for all the interest and enjoyment he has given me in reading his weekly articles. I always look forward to the post which brings the *B.M.J.*, whereas previously I never cared. When time is short I read "Without Prejudice" and skip the rest; but in better times I read your excellent leading articles, the correspondence pages, perhaps an original paper, and quite often parts of the *Supplement*, and leave Pertinax's article until the end as a bonne bouche.

I ought also to thank the one, unknown to me, who conceived the idea most brilliantly of asking Pertinax to write for the *B.M.J.* This not only added to the interest but also did something to improve the journal as an instrument of education. Perhaps many other readers might appreciate a few additional articles of this type in the *B.M.J.*, not entirely confined to the serious reporting or discussion of purely medical or scientific topics.

Thanks are also due to the one who returned the "Contents" to its previous place on the front cover page from the midst of the advertising jungle where it hid itself for a time a year or two ago, so that I have been able to turn in a jiffy to the Pertinax column.

It is with great sorrow that I read his last little four-letter word, *Vale*, and with a tear I wish him well.—I am, etc.,

Conway, Caerns. T. V. TATTERSALL.

SIR,—It is with profound sorrow that I note the demise of Pertinax.

Pertinax was the one thing about the *B.M.J.* that reminded me that it was written by men, not machines. Though he chose to hide his identity, he certainly did not hide his personality. Compared with the facelessness of the editorials, he was a miracle of sustained levity and frequent erudition. It was surely no accident that he was to be found in the middle pages of the journal, a slender lifeline against ennui, a balm for the weary. I disagreed with most of what he said, but at least he was human.

His absence may mean that the intellectual tenor of the journal will approach the colour of its cover.—I am, etc.,

London W.C.1. GRAHAM WORRALL.

Points from Letters

Minister's Cambridge Speech

Dr. J. H. SWAN (London W.13) writes: In the Minister of Health's speech at Cambridge, at the end of last month, he declared himself once again "wholly against National Health charges" and that those who suggested them had "simply not thought the arguments through." He continued along the old predictable lines that health charges would encourage private treatment which would promote "two standards of medical care." . . . If the Minister persists in his dangerously dogmatic attitude the inevitable outcome will be what he most fears—a National Health Service which is a poor second to flourishing private practice.

Providing Information

Dr. DAVID CHASTELL (Broadstairs, Kent) writes: An attitude is growing up where some psychiatrists and their social workers are refusing point blank to reveal any information about patients to other doctors, be they consultant or general practitioner. Recently I wrote fully informing a psychiatrist that a patient had moved 100 miles away from him and was under my care. Despite three letters, he refused to supply me with any information whatsoever unless I obtained the patient's signed consent first. To do this would, I thought, have negated any value therefrom.

Surely it is fundamental teaching, in this country, that a patient ought to be treated as a whole and any practice of good medicine must take account of all facets, not just an "arm," "leg," or chest." No surgeon would dream of refusing information about the aetiology of a scar on the "belly." Is it not often more important to know the aetiology of a scar on the mind?

Obituary Notices

Colonel C. H. REINHOLD, M.C., F.R.C.S.ED., I.M.S.(RET.)

Colonel C. H. Reinhold, one of the best known and highly regarded officers of the Indian Medical Service, died peacefully at Haslemere, Surrey, on 22 July, at the age of 86.

Carl Henry Reinhold was born on 4 December 1880, and received his medical education at Guy's Hospital, qualifying with the Conjoint diploma in 1903. After a period of hospital residency he entered the Indian Medical Service by examination in 1905.

His early military years were served with the old Punjab Frontier Force. In 1911, during a period of study leave, he took the F.R.C.S.Ed. During the first world war he served with distinction in France and Mesopotamia, gaining a mention in dispatches and a Military Cross for gallantry in action. On the civil side of the I.M.S. after the war Reinhold gained a high reputation in many major civil surgeoncies as an all-round clinician, operative surgeon, and district medical administrator. He held such key posts as Meerut and Dehra Dun, and, finally, was much in the public eye as chief medical officer and civil surgeon of New Delhi. On promotion to the rank of colonel he was appointed inspector-general of civil hospitals of the Punjab, retiring in 1937 on account of age. After retirement he served as station medical officer with the R.A.F. at Odiham, and during the second world war was medical officer to the Bank of England at Whitchurch. He later joined the medical board staff of the Ministry of Pensions.

Throughout his service Reinhold was held in high respect by a host of patients and by his brother officers, who, only a few years ago, invited him to preside over the annual service dinner.

Reinhold married in 1918. His wife died three years ago. There were three sons of the marriage, one of whom, trained at Guy's Hospital, died in an accident in America, and one died in infancy. To the surviving son—himself a former Indian Army officer—and grandchildren we extend our sympathy.—G. R. McR.

S. C. GHOSH, M.B., B.S., F.R.C.S.

Mr. S. C. Ghosh, consultant ear, nose, and throat surgeon to the West Bromwich and the Lichfield, Sutton, and Tamworth groups of hospitals, died suddenly at his home in Sutton Coldfield on 25 June.

Saral Chandra Ghosh was born in India, and he received his medical education at Lucknow University, graduating M.B., B.S. in 1930. He came to London in the early 1930s, and worked for a time at the Institute of Laryngology and Otology before moving to Birmingham in 1936, where he was appointed registrar at the Birmingham and Midland Ear and Throat Hospital. In 1940 he was appointed resident surgical officer at the West Bromwich and District General Hospital, where he obtained a wide experience in general surgery. He returned to ear, nose, and throat surgery in 1943, and joined the school health service. He was assistant ear, nose, and throat surgeon to the Birmingham Children's Hospital from 1944 to 1945, when he joined the staff of the Tamworth General Hospital, and the following year was elected to the senior staff. With the advent of the National Health Service in 1948 he became consultant ear, nose, and throat surgeon to the West Bromwich and district hospital group, and to the Lichfield, Sutton, and Tamworth hospital group. He obtained the F.R.C.S. in 1954, and in 1961 was appointed surgeon to the Good Hope General Hospital at Sutton Coldfield.

J. A. writes: Saral Ghosh was interested in all branches of ear, nose, and throat surgery, and only twelve months ago attended a course in Holland on reconstruction surgery of the nasal pyramid. He was obviously delighted to find yet another new field in his specialty, and talked enthusiastically about cases which he had treated. He was, however, particularly interested in neck surgery, and travelled widely, visiting clinics on the Continent and in Scandinavia. He was a scrupulous, painstaking, and neat surgeon, who developed his own techniques, and gladly demonstrated them to anyone who came to watch him work. Saral Ghosh was a shy, retiring, modest man, with little time or interest for medical politics. He devoted all his energies to the care of his patients. His sincerity, charm, and characteristic boyish smile made him many lasting friends, and he will be greatly missed. He leaves a widow and three sons, and we extend to them our deepest sympathy.

L. R. J. writes: Saral Chandra Ghosh was a man of philosophical disposition, shunning controversy, and of a shy nature. He was a genial man and a kindly friend, devoted to his wife and family, and had a wide range of interests which included Freemasonry. He liked working with his hands, as evidenced by his careful surgery, and he even went to evening classes to learn carpentry. He enjoyed tinkering with cars and was a keen gardener, and he also appreciated music, in particular the Indian classics.

C. E. COBB, M.B., B.S., D.T.M.

Dr. C. E. Cobb, formerly in general practice in Basingstoke, Hants, died on 17 July. He was 72.

Charles Eric Cobb was born on 1 May 1895, and was educated at Dulwich College and St. Thomas's Hospital, London. His education was interrupted by the first world war, and he served as surgeon sub-lieutenant, R.N.V.R., from July to December of 1916, when he was temporarily demobilized and returned to complete his medical studies. As a fourth-year medical student he was selected to hold the responsible post of a resident physician at the London Fever Hospital. On qualifying with the Conjoint diploma in 1918 he was appointed casualty officer and resident anaesthetist at St. Thomas's Hospital before returning to active service as a temporary surgeon-lieutenant, R.N. After demobilization in 1919 he joined the Malayan Medical Service, later becoming senior medical officer for the State of Pahang. He took the D.T.M. in 1920 and graduated M.B., B.S. in 1924. He returned from Malaya in 1931, and in 1932 entered general practice in Basingstoke, where he remained for some thirty years. An active member of the British Medical Association, he was a representative at the Annual Meetings from 1945 to 1947, and chairman of the Aldershot and Basingstoke Division from 1945 to 1948. After his retirement from general practice he continued for a time in ophthalmic medical practice until forced by ill-health to give it up.

Charles Cobb was a much liked and popular person, both as a student and naval surgeon and as a doctor in Malaya and among his many patients and friends in Basingstoke and the adjoining village of Sherborne St. John, where he lived after retirement. He leaves a widow, three daughters, and a son, who is a senior registrar in the ophthalmic department at St. Thomas's Hospital, to all of whom we extend our sympathy.—E. J. S. B.

S. C. BARNES, M.B., CH.B.

Dr. S. C. Barnes, a general practitioner in Wirral, Cheshire, died in hospital on 19 February after a short illness. He was 73.

Samuel Crossley Barnes was born in Lowbands, Gloucestershire, on 28 August 1893. He served in the R.A.M.C. during the first world war, but after demobilization he was unable to embark upon his medical career owing to heavy family responsibilities. His was, indeed, a remarkable achievement, as the opportunity to enter medical school did not arise until he had reached the age of 40 years. He entered Liverpool University, graduating M.B., Ch.B. in 1940, at the beginning of the second world war. After serving as house-surgeon at Birkenhead General Hospital, he entered a busy practice in the Wirral. He was actively engaged as a major in the Home Guard during this time. After a short spell in general practice in Formby, Lancashire, Dr. Barnes returned to the Wirral in 1946, and for the next twenty years he devoted his whole life to his patients. He was an excellent clinician and obstetrician, and his standards of medicine were of the highest order, a fact which was recognized when, in December 1950, he was invited to join the Cohen Committee on general practice, on which he served during the next two and a half years.

Dr. Barnes was an idealist who did not spare himself in the interest of his patients.

His capacity for work was prodigious. On one occasion, during a severe influenza epidemic, he worked for three days and nights without any sleep, at the same time more ill than many of his patients. He sacrificed his leisure and in the end his own health, despite much advice to take things more easily, and he continued to work up to a few days before his death. His care of his patients did not end with medicine, and he would spare no effort to help anyone who had genuine problems. Dr. Barnes had a deep interest in the arts, and was widely read. His favourite relaxation was music and he was an accomplished pianist.

Affectionately known as "Sammy," his passing is mourned by many hundreds of his patients. To his widow we offer our deepest sympathy. Her sacrifice and her devotion to his practice enabled Dr. Barnes to succeed in the calling he had longed to serve.—W. G. R.

J. L. BROWN, M.B., B.CH., B.A.O.

Dr. J. L. Brown, a former general practitioner in Birmingham, died in Selly Oak Hospital on 22 July after a brief illness. He was 79.

John Laird Brown was born near Londonderry in 1888, and was educated at the Royal School, Raphoe, University College, Galway, and Queen's University, Belfast, graduating M.B., B.Ch., B.A.O., in 1912. He entered general practice in South Wales, and in 1921 joined his brother, Dr. J. A. Brown, in Stirchley, Birmingham. Over the years he earned the esteem and lasting affection of the patients of his large practice, from which he retired about two years ago.

John Brown was a kindly and genial man, with an outstanding sense of humour, and a great natural aptitude for making friends. The passing of this notable personality will be deeply regretted, not only by his medical colleagues in Birmingham, but by a host of non-medical friends within and beyond the bounds of the city. In the Midlands he was widely known in golfing circles. He had been president of the King's Norton golf club since 1945, having formerly captained the club and acted for a time as its secretary. He was a past-president of the Midland Counties golf association, and a vice-president of the Worcestershire professional golfers association. A staunch Ulsterman, he was a founder member and a past-president of the Birmingham and District Ulster Association. In addition to golf, the cultivation of roses was one of his hobbies, and from this, being the expert he was, he derived great enjoyment and satisfaction.

Dr. Brown's wife, who had been a wonderful partner in their married life, died in 1952. He leaves a married daughter and two sons, the elder of whom is in practice in Malvern ; the wife of the younger son is also a doctor, in medical practice in Birmingham. The sympathy of all his many friends and colleagues will go out to them.—H. C.

H. F. G. HENSEL, M.R.C.S., L.R.C.P.

Dr. H. F. G. Hensel, general practitioner of Milton Abbas, Dorset, died in hospital on 13 July. He was 62.

Henry Frederick George Hensel was born in London on 24 November 1904. He received his education in Birmingham, and later at Nottingham University, where he read botany and pharmacy, becoming a member of the Pharmaceutical Society. After a short time in business he began his medical studies at the London Hospital, qualifying with the Conjoint diploma in 1935. After holding house appointments at the London Hospital and the Poplar Hospital for Accidents he went to Kashmir under the auspices of the Church Missionary Society, working with Sir Henry Holland in Quetta. While in Kashmir he met and married Elizabeth Davis, a King's College Hospital nurse, the elder daughter of the late Mr. William Davis, of Newbury, Berks. His career in Kashmir was cut short by a serious illness which led to his being invalided home in 1939. In 1940 he settled in Milton Abbas with his family and began his career as a country practitioner, which he was to carry on until the time of his death. In addition to his general practice he was also medical officer at Bryanston and Milton Abbey schools, and was a member of the Medical Officers of Schools Association, as well as being a founder member of the College of General Practitioners.

Henry Hensel was a good doctor, and a gentleman in the true sense of that word. His patients became his friends, and he showed equal care and courtesy to gipsies and gentry alike. Quiet and reserved, he was none the less ready to speak out on issues he felt strongly about. His philosophy of life was based on a practical Christian faith, and, although he did not often air his religious views, he averred even in his last illness that it really did work. His main leisure activities were in the garden he created in Milton Abbas, with its fine collection of rare trees and flowering shrubs, which he delighted to show his friends and visitors. He was a keen botanist, and no mean painter in oils.

He will be greatly missed, not only by his family and partners, but also by his wide circle of friends and by the village community in which he lived, and worked, and worshipped. He is survived by his wife and four children, two of whom are doctors. To all of them we extend our deepest sympathy. —C. E. L.

A. H. SHELSWELL, V.R.D., M.R.C.S. L.R.C.P.

Dr. A. H. Shelswell, formerly a general practitioner in Mitcham, Surrey, and of the fourth generation of doctors in his family, died suddenly in retirement at Marnhull, Dorset, on 1 June at the age of 71.

Arthur Hugh Shelswell, son of Dr. O. B. Shelswell, was born on 7 January 1896. Educated at King's School, Canterbury, and at Guy's Hospital, he interrupted his medical education in the first world war to serve in the Royal Navy as a surgeon probationer. He returned to Guy's after demobilization, and qualified with the Conjoint diploma in 1921. After serving as house-surgeon and house-physician at his hospital he took over his father's practice in Mitcham. When the Wilson Hospital, Mitcham, was opened in 1928 he was one of the original members of the medical staff, and served the hospital loyally until he was called up in 1939. He then served throughout the second world war, and for the last two years he was principal medical officer in H.M.S. *Queen Elizabeth*, with the rank of surgeon-commander. After demobilization he returned to Mitcham, where he continued in general practice until July 1958, finding conditions somewhat different from those he had known.

Dr. Shelswell was a keen rugby player, and played for his school, for Guy's Hospital, and for the Barbarians. As a fellow general practitioner, and one of the early medical officers to the Wilson Hospital, I got to know Hugh Shelswell very well. He was honest, kind, and understanding, and incapable of a mean action. He did not appear to be too happy in the National Health Service, and after 10 years he retired. In 1923 he married Eileen Crampton, a doctor's daughter. They were a very devoted couple. She died in March of this year, and there is no doubt that her loss hastened his end.

Our sympathies go to his two daughters, who have lost both parents in such a short space of time.—I. E.

W. LUMLEY, T.D., L.R.C.P.&S.I., L.M.

Dr. W. Lumley, formerly in general practice in Preston, Lancashire, died on 17 July at Stratford-on-Avon. He was 78.

William Lumley was born in Ireland on 28 June 1889, and received his medical education in Dublin, qualifying with the joint diploma of the Royal College of Physicians and the Royal College of Surgeons in Ireland in 1914. During the first world war he served with the R.A.M.C., mainly on ambulance trains and in ships. After demobilization with the rank of captain he became medical officer on the Peking–Mukden railway from 1920 to 1925. On his return to England he set up in general practice at Preston as partner to the late Dr. Stuart Holden. Between the two world wars he joined the 88th Brigade of the Royal Field Artillery, Territorial Army, in which he held the rank of major, and received the Territorial Decoration. He went to France with the battery at the outbreak of the second world war, but was invalided in 1940, and returned to Preston until his early retirement on account of ill-health.

He married Miss Ethel Henley, at one time matron of the Kilkenny Hospital in Ireland, who predeceased him many years ago. He is survived by his only daughter, Maureen Lumley, a matron in the R.A.F. nursing service, and by two sons.—E. A. L.

A. R. W. writes: Bill retired early on account of ill-health, and returned to Ireland to stay with his aged mother, making frequent returns to Preston to see old friends. Bill was a lovable character, with all the Irishman's pawky humour and wit ; sometimes outspoken, and landing himself (temporarily) in hot water, but leaving no rancour.

A memorial service for Sir Eardley Lancelot Holland will be held at Chichester Cathedral, at 2.30 p.m., on 16 August.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending **22 July** (No. 29) and corresponding week 1966.

Figures of *cases* are for the countries shown and for Greater London. Figures of *deaths* and *births* are for the whole of England and Wales (London included), Greater London, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES	1967					1966

* Measles not notifiable in Scotland, whence returns are approximate. † Includes primary and influenzal pneumonia. § Includes puerperal pyrexia.

MEDICO-LEGAL

Antibiotic in Cow's Milk

[FROM OUR LEGAL CORRESPONDENT]

When milk is sold containing an antibiotic it is no defence to a prosecution under the Food and Drugs Act, 1955, that the milk was sold in the same state as it came from the cow.

This is the effect of a ruling of the Divisional Court of the Queen's Bench Division on an appeal by a public health inspector against dismissal by the magistrates at Oswestry of a summons alleging that Central Dairies, Newton, Montgomeryshire, had supplied milk to a retailer which was not of the substance required. Penicillin had been found in two pints of milk. (*Birmingham Post*, 7 July).

The case was remitted to the magistrates for further hearing. In accordance with their rights under the Act, the dairy firm had brought in the Milk Marketing Board, their suppliers, as third parties. The magistrates will have to determine whether primary responsibility for testing milk for antibiotics lies with the Milk Marketing Board or with wholesalers.

Endowment for Private Beds

[FROM OUR LEGAL CORRESPONDENT]

The Court of Appeal has held[1] to be valid a bequest of £35,000 to Barnet Group Hospital Management Committee made on terms that half the fund shall be applied in endowing beds for paying patients in Finchley Memorial Hospital.

As the evidence was that the hospital had 20 paying beds and did not require any more, Mr. Justice Cross in the court below had held that so far as the gift related to the endowment of beds it was invalid. But the Court of Appeal held that "endowment of beds" went beyond the mere physical provision of beds and the buildings to put them in: the phrase included the provision of better beds, bedding, furnishings, decoration and soundproofing of rooms, the provision of telephones and television, sitting- and dining-rooms, and better food. All these purposes were charitable purposes for the benefit of infirm paying patients, and the bequest was valid. The appeal of the Barnet Group Hospital Management Committee was allowed.

MEDICAL NEWS

Peerage for Hospital Chairman

LADY PATRICIA LLEWELYN-DAVIES, Chairman of the Hospital for Sick Children, Great Ormond Street, London, has been made a life peer. Her parliamentary career began in 1950 when she resigned from the Civil Service to become prospective Labour candidate for Wolverhampton, South-west, in 1951. Since then she has contested Wandsworth, Central (1955 and 1959). She was educated at Liverpool College, Huyton, and Girton College, Cambridge. Her husband, LORD LLEWELYN-DAVIES, who is professor of architecture at University College, London, was made a life peer in 1963.

[Universal Pictorial Press

University of the West Indies

Professor D. B. JELLIFFE, director of the Caribbean Food and Nutrition Institute, University of the West Indies, has been appointed honorary professor of community nutrition at the university. Professor Jelliffe qualified from Middlesex Hospital in 1943. After a period in the Sudan Medical Service, he held lectureships in paediatrics at the University College, Ibadan, and in Jamaica. In 1954 he became W.H.O. professor in paediatrics at the All-India Institute of Hygiene and Public Health in Calcutta. He was then appointed visiting professor of tropical medicine at Tulane University, New Orleans. From 1959 to 1967 he held the Unicef chair of paediatrics and child health at Makerere Medical School, Kampala. Professor Jelliffe was elected F.R.C.P.(Lond.) in 1961. He is a member of the W.H.O. expert panel on nutrition. His latest monograph, *The Assessment of the Nutritional Status of the Community*, was published last year.

New Chair at Keppel Street

Dr. R. F. L. LOGAN, reader in social medicine at Manchester University, has been appointed to the Chair of Organization of Medical Care at the London School of Hygiene and Tropical Medicine from 1 October.

Dr. Logan, who is 49, graduated M.B. with honours at Queen's University, Belfast, in 1940. After house appointments in Southampton and Salford he served with the Royal Netherlands Marine. In 1947 as a Nuffield Fellow in industrial medicine he studied adolescent workers with the M.R.C. social medicine research unit under Professor J. N. MORRIS. The same year he took the D.I.H., M.R.C.P., and M.D.(Belf.). In 1950 he organized the university health service in Manchester as lecturer in occupational health. He was awarded a Rockefeller travelling fellowship in 1955 and visited the U.S.A. and Canada. Returning to Manchester, he took up his present readership in social medicine in charge of teaching in the Darbishire House experiment. Since 1963 he has been director of the first medical care research unit and consultant to the World Health Organization. He is joint author of *The Demand for Medical Care*.

M.R.C. Advisory Boards

The Medical Research Council has made the following appointments to its advisory boards as from 1 October: *Biological Research Board*, Professor A. S. V. BURGEN, F.R.S. (Department of Pharmacology, Cambridge University); Professor K. BURTON (Department of Biochemistry, University of Newcastle upon Tyne); Professor P. M. B. WALKER (Department of Zoology, Edinburgh University). Professor J. L. GOWANS, F.R.S. (Sir William Dunn School of Pathology, Oxford), already a member of the board, will succeed Professor W. D. M. PATON, F.R.S., as chairman. *Clinical Research Board*, Professor A. W. KAY (Regius Professor of Surgery, Glasgow University). *Tropical Medicine Research Board*, Professor W. MELVILLE ARNOTT (Department of Medicine, Birmingham University); Dr. D. J. LEWIS (M.R.C. External Scientific Staff, British Museum (Natural History)).

Advice on Hospital Scientific Services

A committee to advise on hospital scientific and technical services in Great Britain has been set up by the MINISTER OF HEALTH and the SECRETARY OF STATE FOR SCOTLAND. Its terms of reference are: "To consider the future organization and development of hospital scientific and technical services in National Health Service hospitals and the broad pattern of staffing required and to make recommendations." The chairman will be: Sir SOLLY ZUCKERMAN, Chief Scientific Adviser to the Cabinet Office. Other members are: Professor A. R. CURRIE, Regius Professor of Pathology, Aberdeen University; Dr. R. GADDIE, Chief Biochemist, the General Hospital, Birmingham; Professor J. E. ROBERTS, Middlesex Hospital, Professor of Physics, London University; Mr. A. B. SCOTT, Secretary, United Manchester Hospitals Board of Governors; Professor J. P. SHILLINGFORD, Hammersmith Hospital, Consultant Physician, and Director, Medical Research Council's cardiovascular research unit; and Dr. S. SHONE, Senior Administrative Medical Officer, Sheffield Regional Hospital Board. The secretary of the committee will be Mr. R. P. S. HUGHES, of the Ministry of Health.

Family Planning Services

The Minister of Health, Mr. KENNETH ROBINSON, has drawn the attention of local health authorities in England and Wales to the National Health Service (Family Planning) Act, which came into force on 28 June (see *B.M.J.*, 6 May, p. 385). He has asked them to review their family-planning arrangements, including the giving of information by health visitors and others in the course of their daily work.

A.M.A. Policy on Abortion

The A.M.A. House of Delegates, at its meeting in June, adopted a statement opposing induced abortions except when:

> "(1) There is documented medical evidence that continuance of the pregnancy may threaten the health or life of the mother, or
>
> "(2) there is documented medical evidence that the infant may be born with incapacitating physical deformity or mental deficiency, or
>
> "(3) there is documented medical evidence that continuance of a pregnancy resulting from legally established statutory or forcible rape or incest may constitute a threat to the mental or physical health of the patient;
>
> "(4) two other physicians chosen because of their recognized professional competence have examined the patient and have concurred in writing; and
>
> "(5) the procedure is performed in a hospital accredited by the Joint Commission on Accreditation of Hospitals."

In adopting the statement, the House recognized that there are many physicians who on moral or religious grounds oppose therapeutic abortion in any circumstances.

Emergency Bed Service

In the year 1966–7 applications for admission to hospital totalled 53,311, compared with 59,496 the previous year. These figures are given in the annual report, which contains a reminder that cases can be accepted by the service only when the patient has been seen by a doctor within the last 24 hours.

British Heart Foundation

Research grants, totally about £77,000, are announced by the British Heart Foundation. They are as follows:

Physiology and Biochemistry of the Heart and Circulation: Professor C. W. M. Adams, Guy's Hospital Medical School, London, £6,875; Dr. G. de J. Lee, Radcliffe Infirmary, Oxford, £11,260; Professor R. J. Linden, Leeds University, £9,050; Dr. G. Manley, Radcliffe Infirmary, Oxford, £1,615; Dr. E. N. O'Brien, Institute of Diseases of the Chest, Brompton Hospital, London, £2,400; Professor A. G. Shaper, Makerere University College, Kampala, Uganda, £2,200; Dr. E. A. Wren, Birmingham University, £382.

Pathology of the Heart: Dr. G. Williams, Manchester University, £3,000.

Fundamental Research on Structure and Function of the Heart: Professor R. Walmsley, St. Andrews University, £4,000.

Pulmonary Heart Disease: Professor J. M. Bishop, Queen Elizabeth Hospital, Birmingham, £7,385.

Surgical Treatment of Coronary Arterial Disease: Mr. J. S. Bailey, Westminster Hospital, London, £2,500.

Development of Artificial Heart Valves: Mr. L. D. Abrams, Queen Elizabeth Hospital, Birmingham £2,500.

New Techniques for Diagnosis and Treatment: Dr. A. Guz, Charing Cross Hospital, London, £6,400; Professor R. E. Steiner, Royal Postgraduate Medical School, London, £3,845.

Problems of Replacement Surgery: Mr. D. Longmore, National Heart Hospital, London, £4,000; Mr. A. E. Thompson and Mr. D. N. Ross, St. Mary's and National Heart Hospitals, London, £4,500; Sir Thomas Holmes Sellors, Mr. D. N. Ross, and Mr. D. B. Longmore, National Heart and Guy's Hospitals, London, £5,000.

Heart Disease in a Tropical Environment: Professor K. L. Stuart, University of the West Indies, Jamaica, £656.

Research workers seeking support for programmes of original investigation are invited to write for an application form to the Administrative Medical Director, British Heart Foundation, Tavistock House North, Tavistock Square, London W.C.1. The closing date for applications is 6 October.

Cambridge Student Health Association

The objects of the Cambridge Student Health Association, which has recently been formed, include the sponsoring of student health education and of research into student health. Dr. BRIAN DAVY is president and Dr. A. A. CRAIGEN is secretary of the association.

U.K. Branch of P.M.A.

At a meeting of Pakistani doctors in London on 15 July at B.M.A. House it was resolved to form a branch of the Pakistan Medical Association in the United Kingdom. The chairman of the organizing committee is Dr. M. A. QADEER KHAN, 18 Leinster Square, London W.2.

People in the News

▶ Professor D. WHITTERIDGE, F.R.S., professor of physiology at Edinburgh University, is to visit the Vallabhbhai Patel Chest Institute, University of Delhi, India, under the Royal Society visiting professorships scheme.

Coming Events

International Union Against Tuberculosis and Royal Netherlands Tuberculosis Association.—International Tuberculosis Conference, 3–7 October, Amsterdam. Details from Conference Secretariat, K.N.C.V., P.O.B. 146, The Hague, Netherlands.

Societies and Lectures

For attending lectures marked ● a fee is charged or a ticket is required. Applications should be made first to the institution concerned.

Wednesday, 16 August

STOKE MANDEVILLE HOSPITAL.—(1) 12.15 p.m., Dr. A. S. Hall: clinical cases. (2) 6 p.m., Dr. M. Mayne: case demonstration.

Friday, 18 August

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. K. M. Citron: clinical demonstration.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the council held on 3 August, with Sir Hedley Atkins, president, in the chair, Sir Miles Clifford, K.B.E., was admitted to the Honorary Fellowship of the College.

The re-election of Mr. Terence Ward as dean of the Faculty of Dental Surgery and the election of Mr. Norman Rowe as vice-dean of the Faculty was reported.

Mr. R. E. Horton, of the United Bristol Hospitals, Mr. F. G. Smiddy, of Leeds General Infirmary, and Mr. R. H. Livingston, of the Royal Victoria Hospital, Belfast, were admitted as members of the Court of Examiners.

Dr. J. R. Batchelor, of Guy's Hospital, was admitted honorary research professor in the College in respect of his appointment as director of the McIndoe memorial research unit, Queen Victoria Hospital, East Grinstead.

The Lady Cade medal for 1966 was awarded to Air Vice-Marshal G. H. Morley.

A Moynihan lectureship was awarded to Professor W. G. Bigelow, of Toronto.

The appointment of Sir Thomas Holmes Sellors as Tudor Edwards memorial lecturer for 1968 was reported.

The Hallett prize was presented to Dr. A. L. G. Peel, of the University of Cambridge.

Handcock prizes were awarded to P. J. Leopard, of Guy's Hospital Medical School, and to R. T. Watson, of St. Thomas's Hospital Medical School (Macloghlin Scholar in 1961).

A diploma of membership was granted to M. H. Mehta.

Deaths

Harwood-Yarred.—On 22 July 1967, at St. Thomas's Hospital, London, William Henry Harwood-Yarred, M.B., aged 90.

Correction

In the leading article "Changed Character of Osteomyelitis" (29 July, p. 255), in the first reference the second author's name should read "CAHEN, I.," and in the second reference the second author's name should read "KIRKALDY-WILLIS, W. H."

New Issues of Specialist Journals

Obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London W.C.1.

BRITISH JOURNAL OF OPHTHALMOLOGY

Contents of the August issue are as follows:

Ciliary Artery Involvement in Giant Cell Arteritis. P. A. MacFaul.
Occult Temporal Arteritis. J. F. Cullen.
Papilloedema in Sarcoidosis. D. Geraint James, M. A. Zatouroff, Joan Trowell, and F. Clifford Rose.
Complicated Cataract Extraction in Fuchs's Heterochromic Uveitis. D. M. Ward and C. T. Hart.
A Method of Trabeculotomy. I. M. Strachan.
Thyroid Disease and Glaucoma. H. Cheng and E. S. Perkins.
Examination for Posterior Subcapsular Cataracts in Patients Treated with Topical Steroids. John Williamson and M. J. Jasani.
Ocular Tension and Diabetes Mellitus. James L. K. Bankes.
Occlusion of a Pre-retinal Arterial Loop. R. B. Harcourt and N. A. Locket.
Orbital Foreign Body Simulating a Malignant Melanoma. C. N. Banks.
Ophthalmological Synopses.
Fixation Device for Central Field Examination. H. M. Symons.
Stand for Applanation Tonometer Prisms. J D. Abrams.
Reviews. Notes.

Volume 51, No. 8. Yearly subscription (12 numbers) inland £8 8s., overseas £9. With *Ophthalmic Literature* and Index (7 numbers) inland £15, overseas £16.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON W.C.1. TELEPHONE: 01-387 4499. TELEGRAMS: *Aitiology, London W.C.1.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs.

ADVERTISEMENT AND SUBSCRIPTION ORDERS should be addressed to The Manager at B.M.A. House, London, or at 415 Bourke Street, Melbourne, Victoria, Australia.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the British Medical Association, B.M.A. House, London, or to the Scottish Secretary, B.M.A. Scottish Office, Drumsheugh Gardens, Edinburgh.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY 19 AUGUST 1967

Pointers

Kwashiorkor: Added iron and high protein diet are valuable aids to recovery, according to Dr. E. B. Adams and colleagues, from Durban (p. 451). Drs. G. C. Cook and M. S. R. Hutt, from Kampala, Uganda, found no evidence that liver disease develops after recovery from treated kwashiorkor in Uganda (p. 454). Leader at p. 446.

Enteropathy in Psoriasis: Professor Sam Shuster and colleagues found the incidence and degree of steatorrhoea were related to the extent of skin involvement (p. 458).

Chronic Bronchitis: Acute exacerbations were related to rhinovirus infection in 14% of Dr. A. C. Stenhouse's cases (p. 461).

Chronic Onychomycosis: Dr. R. R. Davies and colleagues found griseofulvin effective particularly in the finger-nails, and there was no evidence that drug resistance develops (p. 464).

Hypercalciuria: Related to dietary intake according to Dr. M. Peacock and colleagues (p. 469).

Leptospirosis: Major B. Simpson and colleagues found long-term prognosis after acute renal lesions to be good (p. 472).

Intrinsic Factor Secretion: Medical vagotomy did not affect histamine-stimulated output while surgical vagotomy reduced both this and basal output in Dr. J. F. Adams and colleagues' patients (p. 473).

Triploid Chromosome: Hydatidiform mole and coexistent foetus both with this constitution (p. 476).

Autoimmune Disease: Dr. G. L. Asherson's concluding article (p. 479).

Plus ça change: Account of International Congress of Medicine in 1867 by Professor W. H. McMenemey (p. 487).

Is There an Alternative? Mr. A. McWilliam discusses the quinquennial system of financing universities from State funds (p. 489).

Dialysis and Transplantation: Current work reported at Paris Conference (p. 491).

Clamp Like Fingers: Professor R. Y. Calne describes atraumatic clamp for controlling vessels with finger pressure (p. 492).

Pregnancy Tests: To be accepted on request from general practitioners (p. 504). Leader at p. 448.

Negotiations with the Minister: Hospital staffs' work load, research, and mileage allowance are discussed in Joint Second Report (*Supplement*, p. 119).

Accuracy of Mortality Statistics

It is sometimes forgotten that the elaborate mortality statistics published annually by the Registrar General (the latest report[1] runs to nearly 450 pages) depend for the most part on what medical practitioners write on death certificates. Inaccuracy at this stage is inevitably reflected in the final tabulations. From time to time doubts are expressed about the reliability of this information, and interest in the subject has recently been stimulated by the publication of a report from the General Register Office[2] already briefly described.[3]

The clinical staff of 75 selected hospitals were asked to complete dummy death certificates in respect of all patients who died during a six-month period in 1959. Each certificate was completed before the necropsy findings were known, and the stated cause of death was then compared with the pathologist's opinion based on the clinical notes and the post mortem result.

Disagreement was noted in rather more than half the cases, and even when clinicians were "fairly certain" of the cause of death there was disagreement in 44%. According to the pathologists, the clinicians failed to record more than half the biliary cancers, at least a third of the cases of tuberculosis, bronchitis, bronchiectasis, and lymphosarcoma, and nearly a fifth of the lung cancers and peptic ulcers. On the other hand, a substantial proportion of the deaths ascribed by the clinicians to cerebral haemorrhage, cerebral embolism and thrombosis, pneumonia, and diabetes were considered by the pathologists to be due to other causes.

Some caution is needed in using these results to judge the reliability of national mortality statistics. The conditions of the investigation were unusual in that clinicians did not have the help of the necropsy findings which they normally have in about a quarter of the deaths they certify. Furthermore, patients who die in hospital probably present greater problems in diagnosis than do those who die at home. Also relevant is the fact that coroners certify an appreciable proportion of deaths (17% in 1963) and rarely do so without seeking a pathologist's opinion. On the other hand, about half of all deaths occur at home and are certified by medical practitioners who rarely have the advantage of post mortem reports. With all these points in mind it seems fair to conclude that the number of deaths for which the cause is not accurately determined is far from negligible.

Mistakes in diagnosis, however, are not the only cause of inaccuracy of death certificates. In a recent paper,[4] based on the 1,216 deaths which occurred in 1962 in the area of the Oxford Record Linkage Study, M. R. Alderson and T. W. Meade examined the extent of agreement between the principal condition treated in hospital (recorded usually by hospital registrars) and the certified cause of death (usually completed by house-officers). A substantial discrepancy between the two diagnoses was found in 39% of the cases. The authors therefore examined the hospital notes of a random sample of 105 cases. They considered that the principal

© *British Medical Journal*, 1967. All reproduction rights reserved.

condition treated was wrongly stated in 14 and that the certified cause of death was incorrect in 23. Most of the errors were due to failure to distinguish between the main disease and the complications of the disease or incidental conditions.

Even when an accurate diagnosis has been made and has been correctly recorded on the death certificate, difficulty may still arise in the coding of the cause of death. This may lead to serious discrepancies, particularly when international comparisons of mortality rates are attempted. Some idea of the extent of this type of error has recently become available.[5] A sample of 1,000 completed death certificates was sent to five European countries for coding and the results were compared with the coding carried out by the World Health Organization Centre for Classification of Disease in London. The discrepancy rate ranged from 15 to 34%. It seems that although the rules for coding are clearly stated in the International Classification of Disease[6] their interpretation varies from country to country. For example, aneurysm of the thoracic aorta of unspecified cause should, according to the rules, be classified under syphilis, but in some countries where the condition is thought nearly always to be arteriosclerotic these deaths were classified under disease of arteries.

The latest revision of the International Classification of Disease will soon be published and will contain more precise instructions about coding the cause of death when several diagnoses are recorded. This should help to remove some of the errors. But for any substantial improvement in the accuracy of mortality statistics we must look to the doctors who sign the death certificates.

Anaemia in Kwashiorkor

Kwashiorkor is still one of the most important medical problems of childhood in many tropical areas. The anaemia associated with it has long presented a dual challenge, for it is notoriously resistant to therapy and the mechanism by which it is caused is still not generally agreed. The article by E. B. Adams and his colleagues at page 451 of the *B.M.J.* this week is the latest in a long series of studies of these two problems.

When in 1937 attention was first drawn[1] to the anaemia of kwashiorkor it was attributed to protein malnutrition. However, the response of the anaemia to treatment with protein was disappointing, so other causes were sought. The high incidence of helminthic, malarial, and other infections in patients with kwashiorkor led some workers to suggest that it was the secondary infection rather than the kwashiorkor that was responsible for the anaemia. But this explanation was also open to objections. The anaemia of kwashiorkor is found in virtually all regions, whereas the incidence and type of secondary infections vary widely. H. C. Trowell and his colleagues[2] pointed out that infection with hookworms was very common among patients with kwashiorkor in East Africa but that it did not often cause severe anaemia until after the second year of life, whereas kwashiorkor was most frequently encountered before this time. They also observed that kwashiorkor was frequently seen in patients having no evidence of active malaria. Now Adams and his colleagues have completed a study in an area where malaria is rare, and have reached the conclusion that in their patients infection played no part in the production of the anaemia.

It has also been suggested that deficiencies of folic acid, vitamin B_{12}, and iron might be responsible in part for the anaemia. In 1954 Adams[3] reported that considerable numbers of patients with kwashiorkor benefited from treatment with folic acid, but the present study has shown that though folate deficiency may occur in kwashiorkor there is no evidence that the degree of anaemia is related to it. Iron deficiency was also excluded as a prime cause of the anaemia ; Adams and his colleagues found stainable iron in the marrow of all but two of their patients. However, treatment with iron prevented iron deficiency developing when treatment with a high protein diet was given, probably because increased red cell production then drains the iron from the storage depots.

The conclusion reached by Adams and his co-workers is that protein deficiency is the main cause of the anaemia. This and their exclusion of iron deficiency and specific haemopoietic factors as the prime causes support the findings of A. W. Woodruff[4] in his study of the natural history of anaemia associated with protein malnutrition, and further support comes from the work of D. M. Allen and R. F. A. Dean.[5]

How then should this anaemia be treated ? Clearly infections should be eradicated whether or not they have a causative role in the anaemia. Bacterial and malarial infections should be treated at once—respiratory infections are a common cause of death in kwashiorkor. Caution is needed, however, in the use of anthelmintics. Drugs used for hookworm infection tend to produce a variety of complications which can be fatal to ill-nourished children. Unless the condition is mild it is usually best to postpone anthelmintic treatment until recovery from kwashiorkor is well under way.

Iron deficiency may develop during treatment or may be present on admission ; it too should be treated. Again there is a tendency for the remedy to produce nausea when given orally, and Adams and his colleagues recommend that iron-dextran solution should be given by intramuscular injection. Though folate deficiency does not appear to limit haematological progress it is well to guard against it by a daily dose of 15 mg. folic acid. When anaemia is severe a slowly given transfusion of packed erythrocytes may be life saving. Detailed attention to fluid and electrolyte balance is always essential.

Fundamental to the whole treatment is administration of a high protein diet, if need be by intragastric tube and drip feeding. Here the recommendations laid down by Dean and M. Skinner[6] for kwashiorkor of various grades of severity have met widespread acceptance.

The aims of treatment of kwashiorkor are now agreed, and, as Dr. G. C. Cook and Professor M. S. R. Hutt show on page 454, there is no evidence in Uganda that liver disease is a sequel to treated kwashiorkor. Nevertheless, the mass prevention of the condition and widespread availability of treatment are still unsurmounted problems.

Thymic Function and Disease Processes

The thymus arises as a paired structure from the entoderm of the third and fourth branchial pouches. By the end of the second intrauterine month its epithelial nature is clearly evident, and shortly afterwards lymphocytes make their appearance. It rapidly grows in utero, but the greatest maximum weight is not achieved until puberty. From puberty there is a gradual loss of thymic parenchyma and replacement with fat. However, the thymus never completely disappears. The growth curve of the thymus[1] shows that this organ must be of some importance in developmental biology, and that whatever its functions may be they are likely to be most active in early life.

Though it is a lymphoid organ, the thymus differs from other lymphoid tissues both structurally and functionally. Apart from possessing epithelial cells and Hassall's corpuscles and a very high mitotic activity among the cortical lymphocytes, the thymus contains few plasma cells and no lymph follicles with germinal centres. Neither will these latter structures develop after injection of antigen.[2,3] Lymphopoiesis is therefore not effected by antigenic stimulation, and the primary stimulus to proliferation of thymic lymphocytes arises in the thymus itself.[4] Another peculiarity of this organ is the extent and often extreme rapidity with which it will undergo reduction in size in conditions of stress, including serious illness, radiotherapy, the administration of corticosteroids and radiomimetic drugs, and in pregnancy and lactation. This type of involution is due to massive depletion of its lymphoid population and is mediated through the adrenal and pituitary glands.[5,6] The discovery of thymic lesions in patients with thyroid disease, adrenal dysfunction, or acromegaly[7,8] is further evidence that mechanisms for endocrine control may effect thymic structure. Failure to appreciate the effects of stress and hormonal influences, together with the fact that there is a wide variation in the weight of the thymus at different ages,[1] may lead to erroneous diagnoses of hyperplasia, persistent thymus, and aplasia.

It has been known for some time that thymic lesions exist in myasthenia gravis.[7-9] About 10% of patients with this disease have thymomas,[10] and most of the remainder show microscopic abnormalities in the form of medullary lymph follicles with germinal centres, and increased numbers of plasma cells. In the last decade several diseases have been described in association with abnormalities of the thymus. They include the Swiss type of agammaglobulinaemia with thymic aplasia,[11,12] the disgammaglobulinaemias, pure red-cell aplasia and other haemopoietic abnormalities associated with thymoma[13-15] and systemic lupus erythematosus (S.L.E.), and rheumatoid arthritis,[16,17] in which there are derangement of architecture and changes in the epithelial cells. The thymic changes present in myasthenia gravis and S.L.E. are better termed dysplastic[18] in contrast with the true hyperplasia seen in, for example, thyrotoxicosis.[7] The recent report of a child with subacute leucoencephalitis in whom remission was obtained by thymectomy[19] is yet another instance of a disease with autoimmune features and thymic change. It is interesting in this context that damage to the frontal lobes and thymic lesions have previously been described.[20,21]

Some experimental findings are also relevant. In 1944 it was reported that a strain of mice " spontaneously " developed thymic leukaemia and that this process was thymus-dependent,[22] and in 1956 a lymphocyte-stimulating factor was isolated.[23] Experiments with neonatally thymectomized mice established the notion that the thymus is essential to the normal development and function of the lymphoid system. A circulation of lymphocytes between thymus, thoracic duct, lymph nodes, and spleen was suggested, and a thymic hormonal effect demonstrated.[24,25] All the evidence thus points to the thymus playing a key role in the control of immune reactivity.

Furthermore, it has been suggested that there are two centres directing immunity, one being the thymus, which is concerned with cellular immunity, the other being the bursa of Fabricius (a thymus-like structure found in birds) or its equivalent in man—possibly tonsil or appendix—which controls antibody production.[26] Current concepts of thymic function were recently summarized by Burnet.[27] It is suggested that the thymus is the centre of lymphoid-cell differentiation, making immigrant stem cells from the bone marrow differentiate along immunological pathways, and that the immunocytes so formed are differentiated in such a way as to activate the genetic loci associated with antibody production. Another suggestion is that more than one humoral factor is secreted by the thymus, whose effects control lymphopoiesis in the thymus itself and perhaps in bursa-of-Fabricius-

like organs and the viability of immunocytes leaving the thymus to colonize secondary lymphoid organs.

As to the role of the thymus in disease, most of these clinical syndromes are linked with disorders of immunity and production of autoantibodies as in myasthenia gravis,[28-30] systemic lupus erythematosus, rheumatoid arthritis, thyroid disease,[31] and even the red-cell aplasia associated with thymoma.[32] The rudimentary epithelial thymus associated with the Swiss type of agammaglobulinaemia can be considered to be the clinical counterpart of neonatal thymectomy in animals, and there are now more than twenty syndromes in man with disordered production of antibody and in which abnormalities of the thymus, or bursa-like equivalents, or both have been described.[33] So far as diseases with an autoimmune basis are concerned, the role of the thymus is less clear, but two main hypotheses, not necessarily mutually exclusive, have been advanced. Burnet[34] suggests that autoimmunity may result from the proliferation of forbidden clones of immunocytes within the thymus, and regards the presence of lymph follicles with germinal centres in the thymus as evidence of such a process. An alternative hypothesis[35] suggests that chronic thymitis due to an antigen–antibody reaction within the gland itself results in defective thymic function in dealing with autoimmune lymphocytes. The finding of a neuromuscular blocking agent in the thymuses of myasthenic patients[36] is cited as further evidence of deranged function.

As to the association of thymoma with the development of autoimmunity, it has been postulated[35] that the neoplastic process itself initiates autoimmune disease. This supposition is borne out by the common finding of lymph follicles with germinal centres in thymic tissue adjacent to thymoma in myasthenia gravis but not in thymoma alone.[37] So far there is no clinical counterpart to the "spontaneous" thymic leukaemias in mice known to be due to transmission from parent to offspring of a virus,[38] but there is some suggestion that in children with sex-linked congenital agammaglobulinaemia there is increased risk of development of leukaemia and lymphoma.[39]

Thus it can be seen that the role of the thymus in the production of disease is complex, which explains the variable results of thymectomy and the development of autoimmune disease after thymectomy for myasthenia gravis.[40 41] R. A. Good's concept that there are at least two central origins for peripheral lymphoid tissue is attractive, for, as he points out,[42] the proper functioning of these systems would be vulnerable to failure of development, arrest of differentiation, or arrest of stimulus to proliferate, and defects at any of these levels would be expected to cause disorders of immunological function. This hypothesis could also account for the known genetic basis to many of the autoimmune diseases.[43 44]

Tests for Pregnancy

From the time of ancient Egypt, when the urine of a pregnant woman was known to induce the flowering of plants,[1] many tests for pregnancy have been based on demonstrating the presence of increased amounts of chorionic gonadotrophin in the urine. Some of these tests have relied on the response of animals (such as mice, rabbits, rats, frogs, or toads) to the injection of small quantities of urine. Nevertheless, these methods are time-consuming, and the animal colonies which they require are inconvenient and expensive to maintain. Thus for many years workers have been trying to develop an effective in-vitro method for detecting human chorionic gonadotrophin. An immunological technique was tried by W. Liepmann as long ago as 1903,[2] but there was little success in this field until 1960, when four groups of workers independently reported three different immunological procedures. Of these the haemagglutination-inhibition method[3] has been most generally adopted. This uses sheep red cells that have been mixed with human chorionic gonadotrophin, and an antibody to chorionic gonadotrophin that has been prepared in rabbits. To perform the test the antibody is mixed with a small amount of the patient's urine, and then the sensitized sheep red cells are added. If the patient is pregnant the chorionic gonadotrophin present in the urine reacts with the antibody—which is therefore unable to agglutinate the sensitized red cells. If the patient is not pregnant, on the other hand, there is no competition for the chorionic gonadotrophin, and agglutination of the red cells takes place. The result is recognized after two hours from the pattern formed by the cells at the base of the tube ; a similar test, in which latex particles sensitized with human chorionic gonadotrophin replace the red cells, can be performed on a slide in two minutes.

Convenience and economy would be of little value if the haemagglutination-inhibition method were appreciably less reliable than the well-tried Hogben or female xenopus toad test, the accuracy of which may exceed 99%.[4] Comparative studies have shown an accuracy of 97% for the tube test[5] and 94% for the slide test,[6] though in an investigation confined to patients with suspected pregnancy less than 10 days after the first missed period lower degrees of accuracy were observed.[7] In a further study, by J. Powell and his colleagues, it was concluded that an immunological test was definitely superior to a biological method.

For routine work a pregnancy test that can be completed in two hours, obviates the need for an animal colony, costs in reagents only between two and five shillings per patient, is often positive within a week of the first missed menstrual period, yet rivals the accuracy of earlier methods, has not unexpectedly proved popular. The Hogben test is still occasionally used to determine the titre of human chorionic gonadotrophin in patients with hydatidiform mole and choriocarcinoma, and for checking equivocal results, though immuno-assay is increasingly preferred. Nevertheless, the demand for pregnancy tests is now so great that some laboratories are compelled to exercise selection over those patients to be tested. It is impossible to dictate stringent criteria for the choice of patients; the clinician must judge the need, but should indicate the reasons for his decision to the laboratory staff. A circular from the Ministry of Health (see page 504) now recommends pathology laboratories to accept requests for pregnancy tests on referral from general practitioners.

Tests making use of tanned red cells require skill and care for their performance, and interference with the sedimentation pattern of the erythrocytes may result from such commonplace factors as vibration of the tube or the presence of proteinuria.[8] Above all the clinician should appreciate that both the biological and immunological tests detect the presence of human chorionic gonadotrophin or of luteinizing hormone, which is not necessarily due to pregnancy, and the results of these tests must always be interpreted with this thought in mind.

Mao's Medicine

In the course of a civilization that stretches much further back than our own in the West the conduct of affairs in China has often seemed to have an enigmatic quality. The present revolutionary ferment is no exception, and perhaps one of the oddest features of it is that its mainspring should be those two characteristic nineteenth-century immigrants to England, Marx and Engels.

The strident confusion of voices from China today and the difficulty of communications hinder any clear interpretation of events, especially as different parts of that vast country are in conflict with each other over their allegiances. But recently the effect of "the great proletarian cultural revolution" has led to notable changes in that once estimable record of medicine in China, the *Chinese Medical Journal*, published in Peking as the official organ of the Chinese Medical Association. Instead of the 10 or so articles of high clinical and scientific standard to which readers of that periodical were accustomed, the journal under the new title *China's Medicine*[1] is now mostly devoted to political exhortation, while the original articles are reduced to two or three at the back. The article having pride of place in the first issue is headed "China Successfully Conducts Guided Missile–Nuclear Weapon Test," and the second article, which is a speech delivered by Mao Tse-tung himself in 1957, is "On the Correct Handling of Contradictions among the People." An editorial statement announces that "Our people are out to eradicate all the old ideas, old culture, old customs, and old habits of the exploiting classes and foster the new ideas, new culture, new customs, and new habits of the proletariat." It goes on to say that *China's Medicine* will bring its readers:

> "The works of Chairman Mao Tse-tung, the greatest Marxist-Leninist of our era, who has led the Chinese people's revolution from victory to victory.
>
> "Experience in medical research and clinical practice guided by the invincible thought of Mao Tse-tung.
>
> "Reports on implementation of the policy of medicine in the service of the workers, peasants and soldiers, prevention first, and health work in integration with mass movements, especially the prevention and treatment of commonly-seen diseases in the countryside.
>
> "Advances in the synthesis of modern medicine and traditional Chinese medicine.
>
> "Experience in the Patriotic Health Movement among the masses of the people.
>
> "New people and new things on the medical front resulting from the creative study and application of Mao Tse-tung's thought.
>
> "French and Spanish summaries of the main medical articles.
>
> "News and notes and medical activities."

These aims are repeated in the second issue to reach us recently,[2] which also includes at the end two carefully documented articles from the Chinese Academy of Medicine on the treatment of choriocarcinoma.

Clearly the Chinese Medical Association at the time of writing is backing Mao Tse-tung, but to the Western reader such subservience to political inspiration, whatever its source, as *China's Medicine* promises would seem certain to bring great harm to the development and practice of medicine. No doubt the phase will pass, as the corruption of biology by the Michurin–Lysenko movement did in Russia. It may even leave in its wake some real benefit if it concentrates the attention of both medical experts and politicians on the improvement of public sanitation and hygiene in China. But at present there can be little doubt that rational medicine whose aim is to relieve suffering in the individual and the community is going through a difficult time there.

Studies of Platelets

In-vitro tests of platelet behaviour have been used for three main purposes: firstly, to study the basic properties of platelets; secondly, to measure platelet activity in various diseases; and, thirdly, to screen potential antithrombotic agents. Many test methods have been described, but most of them depend on either the ability of platelets to stick to glass surfaces and to each other, or the way in which they change the density of the electrical charge on their surfaces.

H. P. Wright[1] showed that when whole blood was rotated in a glass bulb the platelet count fell progressively, and that this fall could be used as a measure of platelet adhesiveness. A. J. Hellem[2] showed that a similar fall occurred when whole blood passed through a column filled with glass beads. Both these systems depend on an accurate platelet count being done, but they do allow the behaviour of platelets to be studied in their natural suspending medium, whole blood. Platelet adhesiveness, measured by modifications of these techniques, has been shown to be increased in ischaemic heart disease,[3] cerebrovascular disease,[4] multiple sclerosis,[5] and venous thromboembolism.[6] Decreased adhesiveness has been found in uraemia[7] and scurvy.[8] By using Salzman's column method reduced adhesiveness has been demonstrated in von Willebrand's disease,[9] but other methods have given divergent results in this condition.

The second method for studying platelet behaviour measures their ability to stick to each other and form aggregates. G. V. R. Born[10] showed that this could be monitored by measuring the changes which occur in the optical density of platelet-rich plasma as platelet clumps form and disperse. In the preparation of the plasma by differential centrifugation selective recovery of platelets occurs, so the platelets studied may not be representative of those in the whole blood. Many factors have been found to influence aggregation, and there is considerable patient-to-patient and day-to-day variability.[11] Tests of aggregation have therefore proved disappointing in studying individual patients. Nevertheless, they are useful for the diagnosis of thrombasthenia, where none of the usual agents such as adenosine diphosphate, noradrenaline, and collagen induces clumping. Moreover, differences in aggregation between groups of patients have been observed, for after operation[12] and myocardial infarction[13] increased intensity of aggregation develops. A heterogeneous group of persons has also been described[14] whose platelets respond normally to adenosine diphosphate but who show little response to other aggregating agents.

The third method measures the surface-charge density of platelets by determining their electrophoretic mobility. J. R. Hampton and J. R. A. Mitchell[15] showed that agents which cause aggregation induce changes in mobility, while they found that increased sensitivity to adenosine diphosphate and to noradrenaline occurs in a wide range of acute illnesses.[16] A selective increase in sensitivity to adenosine diphosphate alone occurs in patients with ischaemic heart disease, peripheral vascular disease, and with those conditions which predispose to the development of vascular disease.[17] The changes in sensitivity are due to factors in the plasma, and abnormal sensitivity can be conferred on normal platelets by suspending them in fresh plasma from a patient whose platelets are abnormal.

With the exception of thrombasthenia, which is an intrinsic platelet disease, many of the abnormalities detected in platelet behaviour in various diseases could result from changes in other blood constituents, and not from abnormalities in the platelets themselves. For example, the adhesion of platelets to glass depends on the presence of red cells as a source of adenosine diphosphate,[2, 18, 19] and it has been suggested that changes in the function of the red cells might be responsible for some of the variations in platelet adhesion in certain diseases.[19] In multiple sclerosis, where platelet adhesiveness is increased,[5] E. A. Caspary and his colleagues have recently shown that the red cells have an increased osmotic fragility.[20]

None of the above tests is appreciably affected by anticoagulant therapy, and early claims that linolenic acid and clofibrate reduced platelet adhesiveness have not been confirmed,[21, 22] Nevertheless, many drugs used as vasodilators have been shown to inhibit aggregation and to modify the changes in surface charge induced by adenosine diphosphate and noradrenaline.[23] The naturally occurring vasodepressor prostaglandin E_1 has been shown to be a potent inhibitor of platelet activity, both in vitro[24, 25] and in vivo.[25]

Though these in-vitro tests of platelet behaviour are still not sufficiently precise and discriminatory to be used in diagnosis—except perhaps in von Willebrand's disease and thrombasthenia—they have proved of considerable value in the study of the basic properties of platelets. Moreover, they may contribute to the eventual development of potent antithrombotic agents.

Appointment in Surrey

On 27 May the British Medical Guild published an advertisement in the *B.M.J.* recommending doctors not to apply for public health appointments until a firm acceptable offer of an increase has been made in the pay of all public health medical officers. At the wish of the Council of the B.M.A. the *B.M.J.* stopped advertising vacancies for public health appointments from that date.

Most local authorities have made no attempt to fill senior medical posts since the Guild notice was published, and it is known that the advertisement of a number of vacancies of this kind has been postponed until the ban is lifted. The local authorities associations, who appoint the Management Side of Whitley Committee C, have asked[1] to meet the B.M.A. on 17 August, and this suggests that the dispute may be settled before long.

Surrey County Council, however, chose to seek applications for the position of county medical officer of health, and an appointment has been made. This has drawn protests from the B.M.A. and the South-West London and Surrey Local Medical Committee. The B.M.A. wrote to the Chairman of the Surrey County Council asking that the post be readvertised when the Guild notice is withdrawn, and the L.M.C. pointed out that the County Council's action would prejudice the good relationship between the local authority medical services and family doctors in Surrey. The Chairman of the Surrey County Council has agreed to meet a deputation from the B.M.A. but has stated that he sees no prospect of readvertising the appointment.

These reactions by the profession could have been foreseen by the County Council. It was aware that the professional association representing medical officers of health had advised them not to apply for vacancies, that many doctors who might have intended to apply for the post would be placed in a very difficult position, and the doctors in the public health service in Surrey would take exception to the job being offered while the Guild notice was in force. The new appointment will not be taken up until late in November,[2] so there was no need for haste. The County Council's reckless action has provoked a situation to which there is no easy solution.

Observations on the Aetiology and Treatment of Anaemia in Kwashiorkor*

E. B. ADAMS, M.D., B.SC., F.R.C.P.; J. N. SCRAGG, M.D., D.C.H.; B. T. NAIDOO, M.MED.
S. K. LILJESTRAND; V. I. COCKRAM, B.SC.

Brit. med. J., 1967, 3, 451–454

Anaemia has been shown to develop in experimental animals deprived of proteins or essential amino-acids (Cartwright, 1947), but there is little evidence that protein deficiency is ever the cause of anaemia in man. Though protein is the major deficiency in kwashiorkor, there is an inadequate supply of other nutrients and infection is common. It might be expected, therefore, that anaemia in kwashiorkor is multifactorial. Morphological descriptions support this view. In the considerable body of literature which has accumulated its features are reported as normocytic, hypochromic, macrocytic, megaloblastic, or hypoplastic—singly or in combinations—but as yet there is little clear evidence regarding causation, and treatment is largely empirical.

We report here the results of an investigation of the part played in the production of this anaemia by infection and by deficiencies of iron, vitamin B_{12}, and folic acid; speculate on the role of protein deficiency as an aetiological factor; and make recommendations about treatment.

Clinical Materials and Methods

Sixty African children suffering from kwashiorkor were investigated in a ward used specially for this purpose. All had oedema, dermatosis, and lowered plasma proteins (mean albumin 1 g./100 ml.). They were admitted to the series if their haemoglobins were less than 10.5 g./100 ml., without any other form of selection. As controls we used 40 African infants of comparable age and apparently in good nutritional health.

On admission, Heaf tests and *x*-ray examination of the chest were carried out in all cases. Other infections were diagnosed on clinical grounds and confirmed by appropriate pathological tests. Twenty patients were found to be suffering from acute concomitant infection when first seen—namely, pneumonia, which was the commonest, gastroenteritis, and bacillary and amoebic dysentery. All 60 infants were given tetracycline in a dose of 125 mg. six-hourly whether or not there was evidence of acute infection. Despite this, three developed pneumonia in hospital and one later had amoebic dysentery. In seven infants the course of the disease was complicated by measles.

Our haematological methods have been reported elsewhere (Adams and Scragg, 1965), with the exception of serum folate estimations, which were carried out as described by Waters and Mollin (1961), and neutrophil lobe averages, for which we adopted the method of Herbert (1962). Clinical and haematological progress was observed for at least four weeks while the children were on a high-calorie diet of full-strength cow's milk with added glucose and potassium acetate. Feeds were offered four-hourly in unlimited amounts. Supplements of folic acid and vitamin B_{12} were not given except in two infants who required treatment with folic acid during the course of their illness. Six patients needed blood transfusion.

By random selection 32 infants received intramuscular iron dextran (Imferon) in six injections during the first two weeks, the total dose being 9 ml. When comparing the results of this group with those of the remainder we excluded the two patients who were given folic acid and the six who were transfused.

Results

Severity of the Anaemia

The mean haemoglobin on admission and the mean of the lowest levels reached in all cases, together with the controls for comparison, are given in Table I. In most of the infants the haemoglobin level dropped shortly after admission, the biggest fall among those who survived being 3.3 g./100 ml. In almost a quarter of the series (14) the lowest haemoglobin was below 6 g./100 ml. Severe anaemia must therefore be regarded as a common feature of kwashiorkor.

TABLE I.—*Severity of the Anaemia (Hb g./100 ml.)*

Haemoglobin	Controls (40)	Kwashiorkor (60)	
		Admission	Lowest
Mean	10·7	8·0	6·8*
Range	6·5–12·4	4·5–10·4	3·7–10·4
Under 9 g. ..	2	45	60
„ 6 g. ..	0	6	14

* Mean of 39 patients (10 died. Hb did not fall in 11).

Role of Infection

The mean haemoglobin on admission in infants with infection was the same as in those without infection, and there was no significant difference between the means of the lowest haemoglobin levels recorded in the two groups (Table II). It may be concluded, therefore, that infection played no part in the

TABLE II.—*Haemoglobin on Admission in Relation to Infection (Hb g./100 ml.)*

* From the Departments of Medicine and Paediatrics and Child Health, University of Natal, Durban, South Africa.

production of anaemia. This is not surprising, since the infections were mostly acute, whereas it is chronic infection which is likely to cause anaemia.

The presence of infection on admission did not affect subsequent haematological progress. The mean rise in haemoglobin over four weeks in such patients was 1.1 g./100 ml., as compared with 0.82 g./100 ml. in infants without infection. In a group of six suffering from intercurrent infection during treatment, however, the rise in haemoglobin was negligible. As would be expected, the presence of infection decreased the chances of survival: among the 20 infants admitted with infection six died (30%), but only two deaths (15%) occurred in the remainder.

Iron Deficiency

Examination of marrow specimens for haemosiderin showed that iron-deficiency anaemia was uncommon before treatment started (Table III). Stainable iron was present in all patients except two in whom iron-deficiency anaemia was confirmed by the absence of sideroblasts and by the plasma iron patterns. A striking feature of the common plasma iron pattern in kwashiorkor is the diminution of total iron-binding capacity and the high percentage saturation—above 70% in a third of the infants, and complete in one case. The number of controls with apparent iron deficiency (judged on percentage saturation) is also worth noting (Table III).

TABLE III.—*Iron Status on Admission. Bone Marrow Haemosiderin Present in 58 Out of 60 Cases*

Plasma Iron Patterns		Plasma Iron (μg. per 100 ml.)	Saturation (%)
Controls (20)	Mean	46	22
	Range	8–112	3–58*
Kwashiorkor (59)	Mean	51	57
	Range	12–152	8–100†

* 7 under 16.
† 19 out of 59, 70% saturated or more.

We previously drew attention to the characteristic plasma iron pattern in kwashiorkor and the infrequency of iron-deficiency anaemia before treatment is started (Adams and Scragg, 1965). We pointed out that after treatment with high-protein diet the picture of iron deficiency commonly emerges, presumably because there is a rise in total red cell mass and the stores are drained of iron. It was for this reason that we divided the 60 infants in this series into two groups by random selection on admission, treating about half with iron. The results are summarized in Table IV. It will be seen that the use of iron prevented the development of iron deficiency and produced a much better mean rise in haemoglobin at the end of an observation period of four weeks.

TABLE IV.—*Results of Randomized Clinical Trial*

Diet Only	Iron-treated
28 patients, 5 died	32 patients, 5 died
1 iron-deficient on admission	1 iron-deficient on admission
9 iron-deficient after 4 weeks	0 iron-deficient after 4 weeks
Mean Hb rise, 0·28 g./100 ml.	Mean Hb rise, 1·42 g./100 ml.

Iron deficiency diagnosed by absence of haemosiderin and sideroblasts in the marrow and saturation less than 16%.

Incidence of Megaloblastic Anaemia

Examination of the bone marrow for morphological changes showed partial megaloblastic erythropoiesis in 17 infants (28%). In these cases erythropoiesis was predominantly normoblastic in type, but giant metamyelocytes were present in all, and in some there were intermediate megaloblasts as well. None was fully megaloblastic. In this group the neutrophil lobe average was slightly higher (2.93) than it was in those with fully normoblastic erythropoiesis (2.64) and in the controls (2.60).

It is noteworthy, however, that the mean haemoglobin on admission was almost the same (7.9 g./100 ml.) in patients with these bone marrow changes as it was when erythropoiesis was entirely normoblastic (8.1 g./100 ml.), suggesting that megaloblastic erythropoiesis plays no significant part in determining the severity of the anaemia of kwashiorkor before treatment with protein is started.

A point worth noting is the fact that where partial megaloblastic change in the marrow was present on admission the mean haemoglobin rise after four weeks' treatment was virtually the same as in the normoblastic group (see Table V). This occurred irrespective of whether iron had been given or not. Furthermore, the presence of these bone marrow abnormalities on admission did not significantly alter the prognosis: there were 3 deaths among 17 infants with partial megaloblastic erythropoiesis (18%) compared with 7 in the remaining 43 (16%).

TABLE V.—*Effect of Partial Megaloblastic Erythropoiesis on Mean Hb Rise After Four Weeks*

	Mean Hb Rise (g./100 ml.)	
	Iron-treated	Diet Only
Partial megaloblastic erythropoiesis	1·83 (7)	0·56 (5)
Normoblastic erythropoiesis	1·18 (17)	0·05 (13)

Number of cases in parentheses.

Vitamin-B_{12} Deficiency

Table VI gives the results of serum vitamin-B_{12} estimations, from which it is apparent that deficiency of this substance seldom occurs in kwashiorkor, confirming our previous observations (Adams and Scragg, 1962). The high values before treatment are probably related to fatty infiltration of the liver.

TABLE VI.—*Serum Vitamin-B_{12} Levels (μμg./100 ml.)*

	Mean	Range
Controls (22)	519	160–1,500
Kwashiorkor patients:		
On admission (48)	1,089	185–4,000
„ discharge (40)	532	135–1,710

Folic Acid Deficiency

Table VII, which gives the serum folate results, shows that folate deficiency was a common finding. Compared with the controls, a much higher proportion of patients with kwashiorkor had subnormal values, one-fifth being less than 3 mμg./ml. while more than half were under 5 mμg./ml., the upper limits of definite and probable folate deficiency according to Herbert (1966).

TABLE VII.—*Serum Folate Levels (mμg./100 ml.)*

	Mean	Range
Controls (39)	10·7	2·8–24·8 (1 under 3; 4 under 5)
Kwashiorkor patients:		
On admission (54)	5·6	0·4–19·0 (10 under 3; 31 under 5)
At 4 weeks (44)	5·2	0·7–13 (11 under 3)

There was a broad correlation between folate levels and the appearance of the bone marrow. Partial megaloblastic erythropoiesis was observed in 5 out of 10 cases in which the folate was under 3 mμg./ml., in 7 out of 21 with values between 3 and 4.9 mμg./ml., and in 3 out of 23 with normal serum folate activity. The neutrophil lobe average was slightly higher (2.83 mμg.)

among those with low folate levels than it was in the group with normal values (2.6 mμg.) and in the controls (2.6 mμg.).

Nevertheless there was no evidence that the degree of anaemia on admission was related to folate deficiency. The mean haemoglobin in 10 cases in which the folate level was less than 3 mμg./ml. was 8.1 g./100 ml.; in 21 cases with serum folate activity between 3 and 4.9 mμg./ml. the mean haemoglobin was 8.3 g./100 ml., and the same mean was found among the 23 cases with normal folate levels. Moreover, the mean haemoglobin rise over the first four weeks of treatment in those infants who had low serum folate values on admission compared favourably with the mean rise in those infants with normal serum folate levels (see Table VIII). There were no deaths among the 10 patients with serum folates less than 3 mμg./ml., though only one was treated with folic acid.

TABLE VIII.—*Effect of Serum Folate Levels on Mean Hb Rise After Four Weeks*

	No.	Mean Hb Rise (g./100 ml.)
Serum folate on admission <3·0 mμg./ml. ..	9	1·05
„ „ „ „ >5·0 „ ..	14	0·80

Discussion

Role of Protein Deficiency

This is by no means an exhaustive study of the many possible factors which might lead to anaemia in kwashiorkor. We have not, for instance, investigated in depth the role of haemolysis, and we cannot express an opinion on the therapeutic value of vitamin E, for which claims have been made (Majaj *et al.*, 1963; Marvin and Audu, 1964; Sandstead *et al.*, 1965). Nor have we attempted to assess the place of riboflavin, deficiency of which may give rise to anaemia and reticulocytopenia due to red cell hypoplasia (Lane and Alfrey, 1965) though its therapeutic use in kwashiorkor is disputed (Allen and Dean, 1965). We are impressed, however, by the similarity between the anaemia found in protein-deficient Rhesus monkeys (Sood *et al.*, 1965) and our own observations in kwashiorkor, and we believe we have circumstantial evidence to support the opinions of Ghitis *et al.* (1963b) and Allen and Dean (1965) that protein deficiency is the main cause of the anaemia in this disease.

Allen and Dean investigated 100 infants with kwashiorkor in Uganda. Though some of their patients, unlike ours, were infested with hookworm and malaria, the series as a whole was similar. They showed a definite relation between the lowest haemoglobin and the total plasma protein. Though we cannot confirm this from our experience, the facts all seem to link the anaemia with lack of protein. The relation must of necessity remain speculative, since definitive proof is clearly impossible in humans, though in animals the evidence is strong (Bethard *et al.*, 1958; Ghitis *et al.*, 1963a). In the present paper we show that there is no reason to attribute the anaemia found on admission to deficiencies of iron or vitamin B_{12}; and though partial megaloblastic erythropoiesis may be seen on examining the bone marrow, and folate deficiency is not uncommon, it has been pointed out that the degree of anaemia is comparable to that observed among the rest of the patients in whom erythropoiesis was normoblastic and folate levels were within the normal range. Infection has also been ruled out as a major cause of anaemia. Moreover, in this series, and in others we have previously reported (Adams, 1954; Adams and Scragg, 1962, 1965), we have noted a common haematological pattern after treatment with high protein diets, whether there was evidence of concomitant deficiencies or not. The underlying pattern was not related to the use of iron, folic acid, or vitamin B_{12}. The reticulocyte count rises shortly after protein feeding begins; in the present series this occurred as frequently in patients on diet only as it did in those receiving additional iron. The haemoglobin level often drops at first but later rises steadily over a period of many weeks to reach a normal or near-normal value, provided deficiencies of iron or folic acid do not manifest themselves. A typical example of uncomplicated progress to recovery is shown in Fig. 1.

Fall in Haemoglobin and Need for Blood Transfusion

The drop in haemoglobin which occurs soon after protein feeding starts is generally slight, but it may be severe and abrupt. We have assumed, with some justification (Cronje *et al.*, 1961; Adams and Scragg, 1965), that this is partly the result of the expansion in blood volume which follows the rise in plasma proteins. When the fall in haemoglobin is small and anaemia only moderate in degree it can be ignored. An abrupt drop, however, is an indication for immediate blood transfusion. Such episodes are alarming and sometimes herald death. To obviate them requires awareness of their occurrence and constant vigilance, and we therefore advise regular estimations of haemoglobin every five days in all cases. When the initial haemoglobin is less than 6 g./100 ml. transfusion is also a wise precaution. Falls in haemoglobin of 3 g./100 ml. were observed in some infants who survived, and prompt transfusion may have saved their lives. In one case delay in giving blood probably contributed to the patient's death.

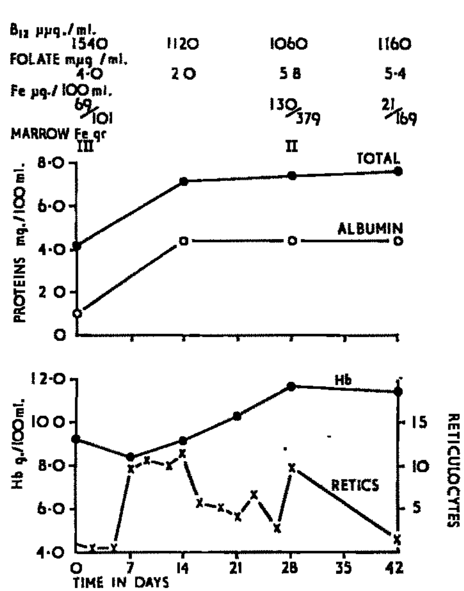

FIG. 1

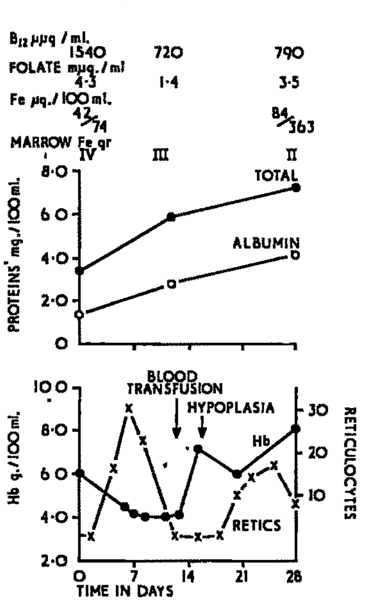

FIG. 2

FIG. 1.—Patient on diet only. FIG. 2.—Patient on diet and given blood transfusion.

It is unlikely that change in blood volume is the only cause of increasing anaemia. In some cases of kwashiorkor the haemoglobin drops because of the development of hypoplasia of the bone marrow (Lien-Keng and Tumbelaka, 1960; Neame and Simson, 1964). Reticulocytes disappear from the peripheral blood and red cell precursors from the marrow, but after a few days or a week the marrow recovers spontaneously, reticulocytosis occurs, and the haemoglobin rises. Such episodes give a double reticulocyte peak to the haematological pattern with a trough of reticulocytopenia in between. In the present series there were five examples, one of which is shown in Fig. 2. Their occurrence raises the question of haemolysis as an aetiological factor, since similar hypoplastic crises are found in haemolytic anaemias. We have not studied this aspect of the problem fully.

In the 60 infants reported here the mean serum bilirubin on admission was within the normal range (0.82 mg./100 ml.) and the initial reticulocyte count was usually only slightly raised (mean 3%), both values being little higher than corresponding control means of 0.54 mg./100 ml. and 1.6%. For this reason it seemed unlikely that the anaemia was predominantly haemolytic. When temporary marrow hypoplasia occurs, however, it does not affect the haemoglobin appreciably unless the red cell survival time is considerably reduced, which has been shown by Hoffenberg (1967, personal communication) to be the case in kwashiorkor. A haemolytic element should therefore be added to the factors which may contribute to the anaemia in this disease, though its importance remains to be clarified.

Iron and Folic Acid as Supplements During Treatment

We previously demonstrated (Adams and Scragg, 1965) that iron deficiency may occur in the recovery phase of kwashiorkor and we have now shown that it can be prevented by administration of iron. Since the detection of iron deficiency with any degree of certainty may require sophisticated tests which are not practicable except as research procedures, we recommend the administration of intramuscular iron to all infants with this disease, a total of 9 ml. of iron dextran being given over the first two weeks. In view of the high proportion of controls who appeared to be iron-deficient, judged on plasma iron patterns, it may well be that the occurrence of iron deficiency in kwashiorkor is not related to the disease itself but to the general iron status of infants in the age group at risk.

The case for supplements of folic acid is less easy to substantiate. It has been seen that partial megaloblastic erythropoiesis and subnormal serum folate levels are not uncommon findings on admission. Though they do not appear to limit haematological progress over the first four weeks, their existence can hardly be regarded with complacency. We have incomplete information about their long-term effects, but occasionally have observed the full picture of megaloblastic anaemia emerging later on. We therefore believe that the addition of folic acid to protein feeding is sound therapy in kwashiorkor, and recommend a routine supplement of 5 mg. thrice daily in all cases.

Summary

From a controlled clinical trial evidence is submitted in favour of the addition of iron to treatment with high-protein diet in kwashiorkor. Though iron-deficiency anaemia is seldom present on the patient's admission, routine treatment with iron prevents its development during the recovery phase.

No evidence was found that vitamin-B_{12} deficiency plays a part in the production of anaemia in kwashiorkor, and there was little support for the view that its severity may be related to the presence of infection, though this complication undoubtedly affects prognosis adversely.

Partial megaloblastic erythropoiesis and folate deficiency are shown to be common findings without playing a major part in the aetiology of the anaemia. Nevertheless, reasons are given justifying the use of folic acid supplements in all cases.

The common haematological pattern during recovery from kwashiorkor, no matter whether haematinics are added or not, suggests that protein deficiency is the main cause of the anaemia.

We thank Professor H. L. Wallace for access to patients under his care and for helpful criticism, and the Medical Superintendent, King Edward VIII Hospital, for facilities. The work was supported by a grant from the Council for Scientific and Industrial Research.

The Liver after Kwashiorkor*

G. C. COOK,† M.D., B.SC., M.R.C.P.; M. S. R. HUTT,‡ M.D., F.R.C.P., F.C.PATH.

Brit. med. J., 1967, 3, 454–457

In many tropical areas a widespread belief persists that malnutrition in infancy often predisposes to hepatic cirrhosis. Evidence has been put forward for a progression from the fatty liver of kwashiorkor (Trowell *et al.*, 1954) to the development of cirrhosis (Davies, 1948; Ramalingaswami, 1964). There is a considerable weight of opinion against such a course of events in man (Gillman and Gillman, 1951; Higginson *et al.*, 1957; Waterlow and Bras, 1957; Brock, 1966). This last view is, however, supported by only one adequate long-term follow-up investigation, which included liver histology (Suckling and Campbell, 1957). In that study, which was carried out in a non-tropical country—South Africa—there was no evidence of cirrhosis in liver biopsy specimens obtained from 20 children five years after recovery from kwashiorkor.

The present investigation was designed to study liver structure and function in 50 African children four years or more after they had had kwashiorkor.

Patients and Methods

Details of the 50 patients investigated are given in Table I. Fifty-five households were visited, but five children were found

* Compared with standard weights and heights for upper-class Baganda schoolgirls (Burgess and Burgess, 1964).

to have died since the first admission: in no case did the history preceding death suggest that severe liver disease had been responsible. Eighteen of the children had been studied in an investigation of the jejunum after recovery from kwashiorkor (Cook and Lee, 1966). All of the 50 children lived within a 60-mile (96-km.) radius of Kampala. They had all been in-patients with kwashiorkor at the M.R.C. Malnutrition Unit, and good case-notes of the previous admission were available. They were taken at random from the admission register of children who left the unit alive. Of the 50 children 33 were from the local Baganda tribe, 14 from the Bahutu tribe of Rwanda, and 3 from other tribes. The severity of the preceding kwashiorkor was divided into four grades on clinical and laboratory criteria (Dean, 1960). Two had had very severe, 30 severe, 14 moderately severe, and 4 mild kwashiorkor.

They were readmitted to the Mulago Hospital for the present follow-up study. Details of the investigation were explained to the parents before the children were admitted. Though there was no evidence of severe malnutrition or vitamin deficiency in any of the children, most had some long-term sequelae of their kwashiorkor, for the mean weights and heights were reduced when compared with standard data for well-nourished Baganda schoolgirls. Weights were reduced more than heights (Table I); the correlation coefficient (r) between individual weights (kg.) and heights (cm.) in the 50 children was +0.893. Twenty-three of the children had also been studied in an investigation which revealed that intravenous glucose tolerance was impaired in most of them (Cook, 1967a), probably owing to pancreatic insufficiency (Cook, 1967b). Three patients had sickle-cell disease and four had the sickle-cell trait. One child had a congenital dislocation of the right hip. Another had had paralytic poliomyelitis since his earlier admission. Parotid enlargement was present in 11 children, slight hepatomegaly in 11, and splenomegaly in 15 (gross in 7). Twenty-one children had hepatomegaly and/or splenomegaly. There was no other clinical evidence of hepatocellular disease in any of the children. Four children with splenomegaly had a strongly positive, and one a positive, fluorescent malarial antibody titre (Voller and Bray, 1962) (Table II). A titre of 1:1,600 was taken to be strongly positive, and one of 1:800 to be positive.

Haemoglobin (Table III) and total and differential white cell count were done in all of the children. Total count was normal in all except five: four had a leucocytosis and one a leucopenia. Twenty-seven had an eosinophilia, accompanied in seven by a neutropenia. Serum bilirubin, aspartate and alanine aminotransferase, and alkaline phosphatase were estimated in all. Total plasma-protein, amino-acid ratio, and hydroxyproline index (Whitehead, 1964, 1965) were also measured (Table III). Three had an abnormality in both the amino-acid ratio and the hydroxyproline index. Brucella agglutinins were estimated in five patients who had granulomata in the liver biopsy specimens. Chest *x*-ray films and straight *x*-ray films of the abdomen were taken in all of the children. The heart shadow was normal in every one; four had pulmonary consolidation (three in the right upper lobe and one in the lingula), and one had bilateral hilar lymphadenopathy. No child had pancreatic calcification.

Aspiration liver biopsies were obtained by an anterior subcostal approach under local anaesthesia with a 1.9-mm. Menghini needle (Menghini, 1958). We believe that this investigation was justified; for in Uganda a considerable proportion of liver biopsy specimens from paediatric patients reveal a treatable disease—such as tuberculosis or schistosomiasis. Indeed, during the present study two cases of active tuberculosis were diagnosed as a result of liver biopsy. There were no complications. All the biopsy specimens were adequate for histological assessment, and all except four were between 1 and 4 cm. in length. They were immediately fixed in 10% formol-saline solution and embedded in paraffin wax. Sections were cut at 5–7 μ. They were stained with haematoxylin and eosin, a reticulin stain, and by Perls's technique for free iron. The presence of malarial pigment was confirmed by demonstrating double refractility under polarized light. All biopsy specimens were examined on several occasions by both authors, and were compared with biopsies from six European children of mean age 10.3 (range 8 to 13) years who had no evidence of liver disease, and who had never lived in a tropical area. All six children had presented with symptoms and signs suggesting liver disease; in three the final diagnosis was extrahepatic venous obstruction, in one Gilbert's disease, and in the other two no conclusive diagnosis was reached, but liver disease was considered to have been excluded.

Results

Liver Histology

Table IV summarizes the results. No evidence of cirrhosis was found in any of the biopsy specimens. None of the abnormalities present in the specimens could be associated with any of the different tribes.

Twenty-one biopsy specimens were relatively normal when compared with the specimens from the six European children

who had never lived in tropical areas. Most of these, however, had mild periportal fibrosis and/or portal infiltration with lymphocytes, and others had, in addition, occasional plasma cells and eosinophils in the portal areas. These changes were not severe enough, however, to produce expansion of the portal tracts. Most specimens showed slight Kupffer-cell hyperplasia and/or hypertrophy, and some showed a slight increase in sinusoidal lymphocytes. Apart from these changes, and the presence of some malarial pigment, nothing else abnormal was found.

The other 29 biopsy specimens showed similar changes, but all of these also had more striking abnormalities when compared with the European children.

Parenchymal Cells

In one biopsy specimen which also had "stellate" fibrosis radiating from the portal areas there was an excess of fat in the parenchymal cells (Fig. 1). That child had had very severe kwashiorkor, and both biochemical tests of current nutritional status were abnormal. Variability in nuclear size and staining with occasional double nuclei was present in 17 biopsy specimens; in 10 there was marked focal nuclear vacuolation. Nuclear vacuolation was also noted in two of the European specimens. Nuclear irregularity was present in one biopsy specimen which also showed "stellate" fibrosis. There was no association between the presence of nuclear irregularity and the severity of the preceding kwashiorkor. No evidence of cell necrosis in any biopsy specimen was found. Of the 17 with nuclear irregularity, five had lowered plasma proteins and five had an abnormality in one of the biochemical tests of current nutrition.

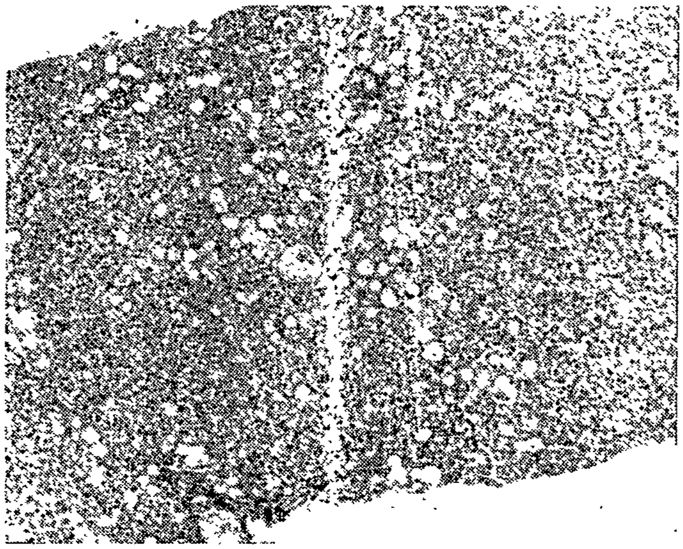

FIG. 1.—Liver biopsy specimen from the only child in the investigation to show an excess of fat in the parenchymal cells. (H. and E. ×20.)

Portal Tracts

Stellate fibrosis spreading from more than one portal tract was found in six biopsy specimens (Fig. 2); one was from a very severe, four from severe, and one from a moderately severe case of kwashiorkor. These six patients had first been admitted between 1.1 and 2.7 (mean 1.7) years of age, and the time between treatment and follow-up was from 5.5 to 8.5 (mean 6.4) years. Three of these cases had an abnormality in one of the biochemical tests of current nutrition (one of them in both tests). In no case was there any widespread linking of the fibrous tissue between adjacent tracts. In several other biopsy specimens a distinct increase in fibrous tissue was present when compared with the controls, but was confined to the tracts. Excessive infiltration with round cells, mainly lymphocytes, causing marked enlargement of several tracts was seen in two specimens.

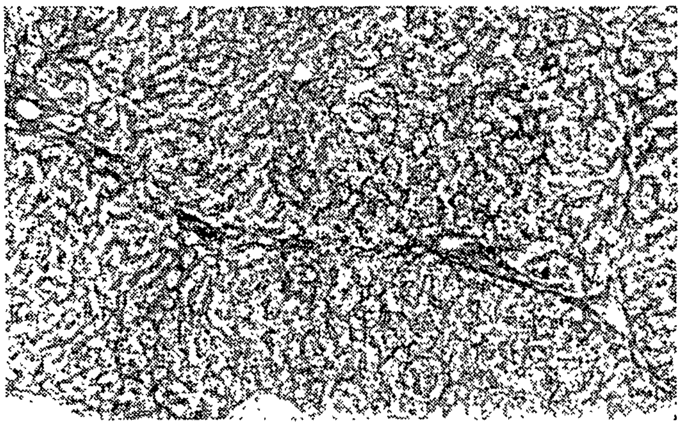

FIG. 2.—Liver biopsy specimen from one of the six children showing "stellate" fibrosis radiating from the portal areas. This specimen showed the most severe change in the present investigation. (Reticulin stain. ×20.)

Sinusoids

In seven specimens sinusoidal lymphocytes were greatly increased in number; four of these cases had splenomegaly and three, moreover, had a strongly positive malarial antibody titre. Malarial pigment was present in five of those seven biopsy specimens. Nine of the 11 specimens with an increase in sinusoidal eosinophils had a high eosinophil count in the peripheral blood. In eight specimens Kupffer cells were greatly enlarged and increased in number; three of these cases had a strongly positive malarial antibody titre.

Malarial pigment was present in the Kupffer cells or in the portal areas of 29 biopsy specimens (Table IV). There was none in the specimens from the children with sickle-cell disease. Twelve children with malarial pigment in the biopsy specimen had splenomegaly. The malarial antibody titre was strongly positive in five and positive in three of these. An excess of free iron in the Kupffer cells was seen in one specimen, from a patient with sickle-cell disease. "Granulomata" were seen in the parenchyma in five biopsy specimens. One was a classical epithelioid granuloma; this case and one other with a granuloma had consolidation of the right upper lobe which was due to tuberculosis. In four cases the "granulomata" consisted of small collections of chronic inflammatory cells grouped around a focus of degenerated parenchymal cells. The possibility that these represent schistosomal granulomata was considered, but ova were not demonstrated on serial sectioning. None of these patients showed a raised brucella antibody titre.

Biochemical Tests of Liver Function

Serum bilirubin was normal in all except one child with sickle-cell disease in whom it was 1.9 mg./100 ml. (normal range <1 mg./100 ml.). Serum aspartate and alanine aminotransferase were normal in all except one child, in whom they were slightly raised (normal range <40 units). Serum alkaline phosphatase was higher than the normal adult range in all except 11 children (mean 19.3, range 7–36 King–Armstrong units). Levels in normal children are usually elevated when compared with the adult range of 3–13 units (Varley, 1962).

Discussion

The only permanent abnormality in the 50 liver biopsy specimens was "stellate" fibrosis in six; in none of these was there a disturbance in the normal liver architecture. It is impossible from this study to relate this fibrosis to the past malnutrition. There was no evidence of cirrhosis, and all biopsy specimens were adequate for histological assessment. The cause of the focal variation in nuclear size in the parenchymal cells is unknown, but was less marked in the present series than in a random group of adult Ugandan African inpatients studied at the Mulago Hospital (Cook and Hutt, 1967). It can be a non-specific result of increased cell turnover (Popper and Schaffner, 1957), and also occurs in malnutrition, as deficiency of riboflavine and pyridoxine has been shown to produce gross nuclear irregularity in the hepatic parenchymal cells of the baboon (Foy *et al.*, 1966). There is, however, no good reason to incriminate current malnutrition in the present study.

Apart from slight portal changes, the only consistent difference between the biopsy specimens in this follow-up study and those from the European children was in the reticuloendothelial components, especially the Kupffer cells. These changes are probably due to parasitic diseases, especially malaria. Malarial pigment was found in the Kupffer cells and/or portal areas in approximately 60% of the biopsy specimens, of whom less than half had splenomegaly and only eight had a positive or very positive malarial antibody titre. In three children there was an association between splenomegaly, increased sinusoidal lymphocytes, and a strongly positive malarial antibody titre. Gebbie *et al.* (1964) have reported a significant association between gross splenomegaly, an increase in sinusoidal lymphocytes, and a strongly positive malarial antibody titre, but without malarial pigment in the liver biopsy specimen ; this probably represents an unusual reticuloendothelial reaction to chronic malarial infection.

This study, despite the fact that at a follow-up examination some of the children were still malnourished and others had evidence of anaemia, malaria, tuberculosis, and other infections, demonstrates that, apart from a few differences which are presumably reversible, liver histology of most Ugandan children after kwashiorkor is very similar to that of European children who have not lived in the tropics.

Despite the widespread belief in many tropical areas that infant malnutrition may account for cases of cirrhosis in later life, the present study in tropical Africa confirms the view of most other workers (Higginson *et al.*, 1957 ; Suckling and Campbell, 1957 ; Bras, 1961) that treated kwashiorkor does not predispose to permanent liver damage. The possibility that prolonged untreated kwashiorkor may proceed to cirrhosis (Davies, 1948 ; Ramalingaswami, 1964) cannot be eliminated by the present study. Most of the children studied had, however, had severe kwashiorkor, and in some cases this had probably been present for a year or more. Only one biopsy specimen still contained an excess of fat in the parenchymal cells. Davies (1951) has suggested that the development of cirrhosis may be a delayed phenomenon and takes place only after the disappearance of fat in kwashiorkor. While this is possible, the absence of any evidence of cirrhosis in six biopsy specimens taken 10 years or more after the treatment of severe or very severe kwashiorkor indicates that progression to cirrhosis must be a rare occurrence. Since it is not possible to obtain an accurate estimate of either the frequency of recovery from untreated kwashiorkor or the overall incidence of adult cirrhosis in Uganda, it must be questioned whether a large enough number of cases has been studied to rule out progressive liver disease in some children after kwashiorkor.

The results of the present investigation apply only to Uganda. There is evidence that liver pathology in kwashiorkor may vary in different areas. In New Guinea, atrophy and vacuolation of parenchymal cells is more obvious than the fatty infiltration (Venkatachalam and Ivinskis, 1957 ; Bailey, 1966) which is so consistent a finding in Uganda.

High serum alkaline phosphatase levels were found in approximately 75% of the children, owing presumably to increased osteoblastic activity in bone.

The good general nutritional status of most of the children here studied after recovery from kwashiorkor, but while continuing to live in the poor socio-economic environment in which they developed kwashiorkor, is striking (Suckling and Campbell, 1957).

Summary

Hepatic histology and biochemical tests of liver function have been studied in 50 Ugandan children, 4.0 to 11.3 (mean 7.0) years after admission to hospital with kwashiorkor. The kwashiorkor had been severe in 32 of the children.

Liver biopsy specimens all showed slight differences when compared with biopsies from six European children who had never lived in tropical areas. Six patients had some " stellate " fibrosis radiating from the portal areas, and in one case there was an excess of fat in the parenchymal cells, but in none was there any evidence of cirrhosis or progressive liver disease.

The liver-function tests gave normal results in most. Serum alkaline phosphatase was elevated, compared with adult levels, in 39 of the children.

There is no evidence from this study that progressive liver disease and cirrhosis are long-term sequelae of treated kwashiorkor in Uganda. The possibility that cirrhosis may follow prolonged *untreated* kwashiorkor has not been eliminated.

We thank Mr. Y. M. Semindi for finding the children for this investigation, and Drs. R. A. Tozer and N. J. Mody for the haematology and liver-function tests respectively. Mr. G. R. Howells was responsible for the plasma proteins and biochemical tests of nutritional status, and Dr. D. E. Wykoff for the fluorescent malarial antibody reactions. Dr. P. J. Scheuer, of the Royal Free Hospital, London, sent us the liver biopsy specimens from the six European children that were used as controls. We are grateful to Professor R. A. McCance, F.R.S., for valuable discussion concerning the manuscript.

Small Intestine in Psoriasis

SAM SHUSTER,* M.B., PH.D., M.R.C.P. ; A. J. WATSON,† M.D., M.C.PATH. ; JANET MARKS,‡ B.A., B.M., M.R.C.P.

Brit. med. J., 1967, 3, 458–460

We have shown that patients may develop an enteropathy as a result of extensive skin disease (Shuster and Marks, 1965). Some of the patients whose cases we described had psoriasis, and so it became important to find out whether bowel abnormalities were a common feature of this disease.

Patients and Methods

Twenty-three female and 19 male patients were studied. Their ages ranged from 15 to 72 years. The total length of history of psoriasis ranged from 3 weeks to 50 years, and the duration of the most recent episode from 1 week to 20 years. All patients had been admitted to hospital for treatment and were studied consecutively, apart from a few who declined the investigation. None of the patients had a history of diarrhoea or bulky stools. The extent of the rash was assessed visually on admission.

Faecal fat excretion was measured in 26 patients. With the patient on a normal ward diet, which was estimated to contain about 100 g. of fat a day, faeces were collected for five consecutive days. The mean daily faecal fat excretion was measured by the method of Van de Kamer, ten Bokkel Huinink, and Weyers (1949), a mean fat excretion of more than 5 g. being regarded as abnormal.

D-*Xylose absorption* was measured in 10 patients. After an overnight fast 25 g. of D-xylose was given and urine was collected over the next five hours. In some cases a sample of blood was taken two hours after the dose of sugar. Xylose in the blood and urine was measured by the method of Roe and Rice (1948), excretion of less than 4.1 g. of xylose in the urine in five hours being regarded as abnormal (Fourman, 1948).

Mucosal Biopsy of Small Intestine

With the use of a Crosby capsule (Crosby and Kugler, 1957) a peroral biopsy specimen of small-intestinal mucosa was obtained from 26 patients, including 12 who had had a faecal fat examination. The position of the capsule was first verified radiologically ; in most cases it was in the proximal loop of the jejunum, but occasionally it was in the fourth part of the duodenum. The specimen was retrieved with the minimum of delay and was transported to the laboratory in ice-cold buffered sucrose solution (0.22 M). With the aid of a stereoscopic dissecting microscope the specimen was then spread out, mucosal surface upwards, on a flat piece of cellulose sponge and divided in two. One piece was immediately frozen by dropping it in liquid nitrogen and was stored at −70° C. in a small airtight container for subsequent histochemical examination. The interval between the firing of the capsule and the quenching of the selected part of the biopsy specimen in liquid nitrogen ranged from 7 to 10 minutes.

The remaining part of the specimen was fixed in 10% formol-calcium for at least 24 hours. Mucus and intestinal debris were then gently removed from the mucosal surface by means of a soft brush, and the mucosa was examined through the dissecting microscope and photographed. After processing through to paraffin wax, histological sections were cut at a thickness of 5 microns. Care was taken to ensure that the sections were cut in a plane perpendicular to the muscularis mucosae in order to obtain a true measure of villous height in relation to the crypt depth.

Correct orientation in the paraffin block was facilitated by the method of fixation, which prevented the specimen from becoming curled or folded. Finally, the sections were stained by various methods, including haematoxylin and eosin, and the periodic-acid–Schiff method.

Dissecting Microscope Appearances

We have followed the terminology of Booth, Stewart, Holmes, and Brackenbury (1962). Finger-shaped villi are self-explanatory. Leaves are a heterogeneous group of villi which are broadened in one cross-sectional diameter. Straight mucosal ridges appear to be an exaggeration of the leaf-shaped forms and the dividing line between them is arbitrary. We define ridges as having a ratio of width to height of greater than three to one. Ridges which pursue a winding course are described as convoluted. A mucosa from which all villi and ridges have disappeared is conventionally described as flat.

Histological Appearances

Partial villous atrophy (Doniach and Shiner, 1957) is the histological counterpart of a convoluted mucosa as seen by the dissecting microscope (Booth *et al.*, 1962). In normal jejunal mucosa the villi are at least twice as tall as the crypts are deep (Hourihane, 1966), and we consider partial villous atrophy to be present when there is shortening of the villi, with or without lengthening of the crypts. This is usually accompanied by an increased number of plasma cells and eosinophils in the lamina propria, and sometimes the surface epithelium is infiltrated by lymphocytes. Occasionally there are foci of irregularity of the surface epithelium similar to that found in subtotal villous atrophy.

Classification

Our classification is based on the stereomicroscopical and histological appearances and is summarized as follows:

(1) Normal: Fingers and narrow leaves.

(2) Equivocal: Broad leaves and short straight ridges. May show increase of chronic inflammatory cells in lamina propria.

(3) Abnormal: (*a*) *Convoluted.* Predominance of angulated ridges. Surface epithelium focally abnormal, increased inflammatory cells, and partial villous atrophy. (*b*) *Flat.* No villi, but mosaic pattern and prominent crypt openings. Surface epithelium abnormal, with increased inflammatory cells.

‡ Lecturer in Dermatology, Royal Victoria Infirmary, Newcastle upon Tyne 1.

Histochemical Studies

Frozen sections from the unfixed material were cut at a thickness of 10 microns in a cryostat cabinet maintained at a temperature of −20° C. *Leucine aminopeptidase* was demonstrated by the method of Nachlas, Crawford, and Seligman (1957) L-leucyl-4-methoxy-β-napthylamide being used as substrate (Rosenblatt, Nachlas, and Seligman, 1958). *Non-specific alkaline phosphatase* was demonstrated after the method of Burstone (1958a) with naphthol-ASMX-phosphate as substrate. *Adenosine triphosphatase* was demonstrated after the method of Padykula and Herman (1955) with $CaCl_2$ in the incubating medium at a concentration of 0.227 M. *Non-specific acid phosphatase* was demonstrated by the method of Burstone (1958b) with naphthol-ASMX-phosphate as the substrate. *Succinate dehydrogenase* was demonstrated after the method of Nachlas, Tsou, de Souza, Cheng, and Seligman (1957). *Glucose-6-phosphate dehydrogenase* was demonstrated by the method of Hess, Scarpelli, and Pearse (1958) with the use of MTT tetrazolium salt. *Non-specific esterase* was demonstrated by the method of Novikoff and Goldfischer (1961).

Results

Fig. 1 shows that 15 of the 26 patients examined excreted more than 5 g. of fat a day in their faeces. Both the incidence and the degree of steatorrhoea were clearly related to the extent of the psoriasis. There was no apparent relation to age, sex, and total duration of psoriasis, or to the duration of the most recent episode. D-Xylose excretion was abnormal in 4 of the 10 patients in whom it was measured, and three of these abnormal results were in patients with steatorrhoea (Table I).

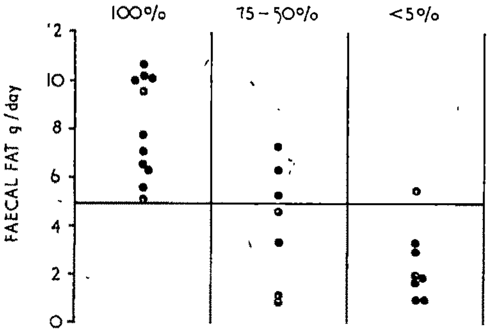

FIG. 1.—Relation between faecal fat excretion and proportion of skin surface affected by psoriasis.

The stereomicroscopical appearances of the small-intestinal mucosa are summarized in Table II. In 12 patients (46%) the mucosa was frankly abnormal with a convoluted appearance (Fig. 2) and histologically showed partial villous atrophy. Most of the abnormal mucosae were found in the younger age group ; none of the patients had a flat mucosa. Unlike the steatorrhoea, the degree of mucosal abnormality was not apparently related to the extent of the psoriasis (Fig. 3).

Normal	Equivocal	Abnormal	
		Convoluted	Flat
10	4	12	0

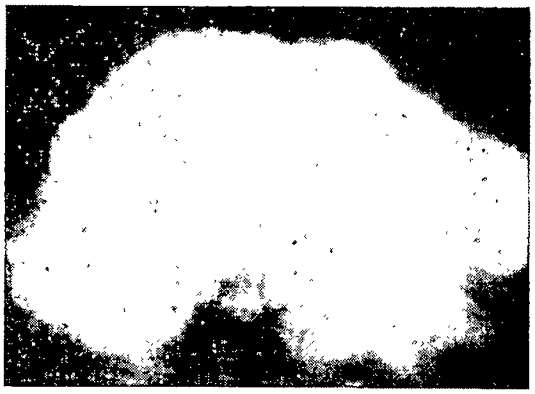

FIG. 2.—Dissecting microscope (×12) appearance of convoluted jejunal mucosa from patient with psoriasis.

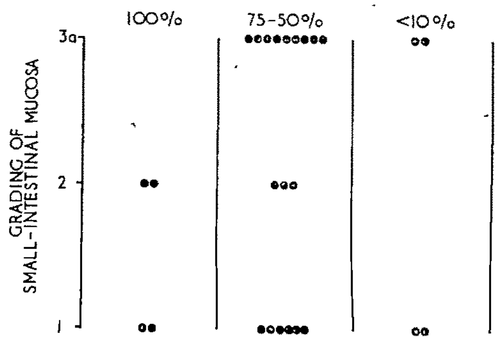

FIG. 3.—To show lack of correlation between mucosal involvement and proportion of skin surface affected by psoriasis.

An abnormality was noted in 12 of the 24 patients whose mucosal biopsies were examined for enzyme activity. This abnormality occurred mainly in patients with a convoluted mucosa. The columnar cells of the surface epithelium covering the free ends of the villi showed loss or inhibition of three membrane enzymes associated with the brush borders of the cells—that is, leucine aminopeptidase, non-specific alkaline phosphatase, and adenosine triphosphatase (Fig. 4). The activity of these enzymes was normal in the brush border other than at the free ends of the villi. Furthermore, the affected cells showed no abnormality in the activity or distribution of the other enzymes studied. In one patient a second biopsy taken six weeks after the first again showed the abnormality. The affected cells showed no unusual features in haematoxylin-and-eosin-stained paraffin sections, and the brush borders gave their usual deep staining reaction with the periodic-acid–Schiff method.

Discussion

Steatorrhoea is common in patients with psoriasis, and this disease and eczema are the main known causes of dermatogenic enteropathy (Shuster and Marks, 1965 ; Watson, Marks, and Shuster, 1967 ; Shuster, 1967a, 1967b). In the present study a convoluted mucosa, together with a histological appearance of partial villous atrophy, was found in 12 out of 26 patients with psoriasis. Though a convoluted mucosa has been found in apparently normal Asians living in India (Baker, Ignatius, Mathan, Vaish, and Chacko, 1962) and Singapore (England and O'Brien, 1966), it was not found in Europeans living in the same area. In a recent study of malabsorption in Scotland (Girdwood, Williams, McManus, Dellipiani, Delamore, and

Kershaw, 1966) none of the 52 control subjects showed a ridged or convoluted jejunal mucosa. It appears, therefore, that our finding of a convoluted mucosa in 46% of our patients with psoriasis is significant. Though none of our patients had a flat mucosa with subtotal villous atrophy we would not wish to exclude the possibility that this may occur.

The steatorrhoea is closely related to the extent of skin involvement (Fig. 1), whereas the mucosal abnormality is not so related (Fig. 3). It is likely, therefore, that there is no relation between degree of steatorrhoea and severity of mucosal abnormality, though our present data on this point are incomplete.

The enteropathy of psoriasis is characterized, therefore, by steatorrhoea with partial villous atrophy or an apparently normal mucosa. In this respect psoriatic enteropathy resembles tropical sprue rather than coeliac disease (England and O'Brien, 1966), as do other forms of dermatogenic enteropathy (Shuster, 1967a, 1967b; Watson *et al.*, 1967).

Many of the biopsy specimens were found to have lost activity of membrane enzymes in the brush borders of the absorptive cells over the free ends of the villi. The possibility of an artifact cannot be completely excluded, though we have been unable to incriminate any variation in our laboratory procedures. In one patient two biopsies were taken at an interval of several weeks and the abnormality was present in both. The site of the abnormality raises the possibility that it has resulted from the action of the intestinal contents on the cell surface. Alternatively there may be some intrinsic abnormality of the epithelium. Though this histochemical abnormality has been found most commonly in patients with psoriasis, it has also been seen in a few patients with eczema, pemphigoid, and dermatitis herpetiformis (unpublished observations), and further investigations are in progress.

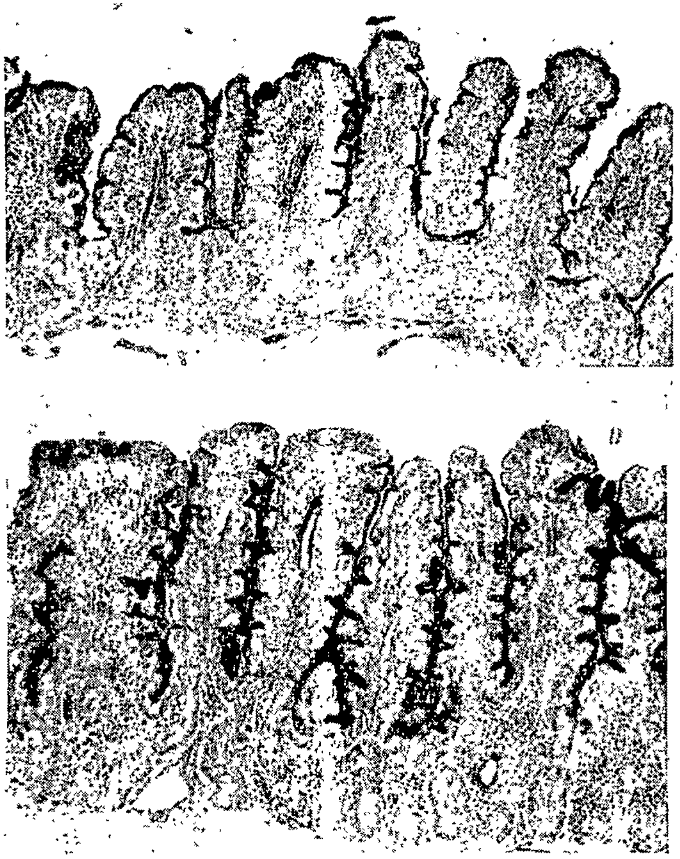

FIG. 4.—Microscopical appearances (×63) of jejunal mucosa from two patients with psoriasis. Above: normal distribution of adenosine triphosphatase activity in surface epithelium of villi. Below: loss of adenosine triphosphatase activity in surface epithelium over free ends of villi.

As with the other forms of dermatogenic enteropathy the immediate cause of the intestinal disorder of psoriasis is speculative (Shuster, 1967a, 1967b). Since the incidence and degree of the steatorrhoea are related to the extent of the skin disease, and since it regresses when the rash is treated topically (Shuster and Marks, 1965), the steatorrhoea is clearly secondary to the skin disease. We do not yet know whether the jejunal mucosa likewise reverts to normal after treatment.

The true incidence and severity of psoriatic enteropathy are unknown; the findings in the present study may reflect the severity of the rash in patients referred to our unit, and much further work will need to be done to define the practical importance of psoriatic and other dermatogenic enteropathies.

Summary

Small-intestinal structure and function were investigated in patients with psoriasis. Faecal fat excretion was measured in 26 and D-xylose absorption in 10; jejunal biopsy appearances were studied in 26. The incidence and degree of steatorrhoea were related to the extent of skin involvement. A convoluted appearance was found in 46% of the jejunal mucosae examined, and a number of these showed a loss of enzyme activity in the brush border of the absorptive cells at the free ends of the villi.

We are grateful to our colleagues at the Royal Victoria Infirmary and the North-east Region for referring patients to us. We are also grateful to Professor A. L. Latner, in whose department the fat and xylose estimations were carried out. We wish to thank Mr. J. R. Maclennan and Mr. J. A. Stewart for valuable technical assistance.

The work was supported by a grant from the Medical Research Council, which we are happy to acknowledge.

Rhinovirus Infection in Acute Exacerbations of Chronic Bronchitis: A Controlled Prospective Study*

A. C. STENHOUSE,† B.MED.SC., M.B., M.R.C.P., M.R.A.C.P.

Brit. med. J., 1967, 3, 461–463

Natural rhinovirus infection in adults is usually associated with an afebrile coryzal syndrome (Hobson and Schild, 1960; Hamre and Procknow, 1961; Reilly *et al.*, 1962; Forsyth *et al.*, 1963), and, depending on the population studied, rhinoviruses as a group are associated with 8 to 25% of minor upper respiratory illnesses in adults and from 5 to 20% of such illnesses in children (Tyrrell and Bynoe, 1961; Johnson *et al.*, 1962; Kendall *et al.*, 1962; Bloom *et al.*, 1963; Hamparian *et al.*, 1964). Forsyth *et al.* (1963) found in Servicemen from whom rhinoviruses were isolated that 50% experienced chest pain and 86% reported a cough. Taylor-Robinson *et al.* (1963) and Hamparian *et al.* (1964) each reported the isolation of a rhinovirus from an adult with bronchitis. In the collaborative study on the aetiology of acute respiratory infections in Great Britain from 1961 to 1964, 179 patients were reported as having bronchitis. No indication was given regarding the age of the subjects, but 23% were associated with infective agents and in four instances rhinoviruses were isolated (Medical Research Council, 1965b). In a direct study of 15 chronic bronchitis patients over a period of two and a half years, Eadie *et al.* (1966) studied 75 acute respiratory illnesses and reported the isolation of 12 rhinoviruses. Eleven rhinoviruses were isolated from 47 illnesses affecting the chest, whereas only one rhinovirus was isolated from 28 illnesses not affecting the chest. The only other study of acute exacerbations of bronchitis which employed techniques for rhinovirus isolation failed to detect these agents (Carilli *et al.*, 1964).

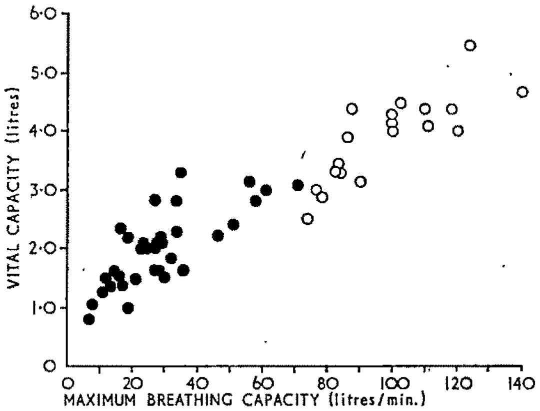
The purpose of this paper is to report the findings of a controlled prospective study designed to determine the significance of rhinovirus infection on the aetiology of acute exacerbations in patients with chronic bronchitis and to describe the clinical picture associated with such infections.

Materials and Methods

Clinical

Thirty-four patients attending the bronchitis clinic, the Royal Hospital, Sheffield, and 19 control subjects enrolled from the staffs of the Sheffield Fire Board and Lodge Moor Hospital, Sheffield, were studied between 18 August 1964 and 1 May 1965. Each patient and subject completed the short questionary on respiratory symptoms (*Brit. med. J.*, 1960) approved by the Medical Research Council Committee on the Aetiology of Chronic Bronchitis. The chronic bronchitis patients fulfilled the criteria for chronic bronchitis as defined by the American Thoracic Society (1962) and Medical Research Council (1965a), and they were clearly able to distinguish between quiescent and exacerbation periods. They comprised 31 men and three women, with a mean age of 61 (range 51 to 73) years. On the basis of the subclassification suggested by the Medical Research Council (1965a) one patient was classified under simple chronic bronchitis, and of the 33 who exhibited airways obstruction, 5 produced mucopurulent sputum and 28 mucoid sputum. The control subjects, comprising 2 women and 17 men with a mean age of 51 (range 32 to 60) years, were shown on the basis of questionary findings and ventilatory function studies to be free of chronic bronchitis or other respiratory disease.

Subjects of both groups were seen at monthly intervals and in addition were asked to report as soon as possible after the onset of an acute infection of the upper or lower respiratory tract. On each occasion that a subject was seen a clinical form was completed. The presence of any upper or lower respiratory tract symptoms during the previous month and the state of the subject at the time of completion of the form were noted. In the chronic bronchitis patients the nature and amount of sputum produced, together with the occurrence of wheeze and shortness of breath, were recorded invariably, and at hospital visits the maximum breathing capacity and the vital capacity were measured by a Poulton Barry SP126 (McKerrow *et al.*, 1960). The mean vital capacity and maximum breathing capacity in the chronic bronchitis patients and control subjects are shown in the Chart.



Mean vital capacity and maximum breathing capacity in chronic bronchitic and control groups. ● = Chronic bronchitis patients. ○ = Control subjects.

The term "acute exacerbation of chronic bronchitis" embraces a spectrum of clinical disorders and was defined in this study as "an alteration in the quiescent state of the patient with an increase in either the quantity or purulence of the sputum."

Virological

On each occasion that subjects were seen a throat swab was obtained and a nasal washing with phosphate-buffered saline made. The throat swabs and nasal washings were placed in a transport medium containing 10% bovine serum albumin and kept at 4° C. Specimens were either inoculated into tissue-culture tubes within three hours of collection or frozen at −70° C. and stored until tested. Sputum specimens obtained from bronchitic subjects were placed at 4° C. for three hours and rendered non-toxic for tissue culture by emulsification in transport medium. They were then centrifuged at 2,000 r.p.m. for 30 minutes and the supernatant fluids stored at $-70°$ C. Blood was obtained by venepuncture, and after separation the serum was stored at $-20°$ C.

* This study is included in material to be presented in a thesis as partial fulfilment of the M.D. degree of the University of Otago, New Zealand.

† Wellcome Research Fellow, University Department of Medicine, the Royal Hospital, Sheffield, and the University of Sheffield, Virus Research Laboratory, Lodge Moor Hospital, Sheffield. Present address: Wellcome Virus Research Laboratory, Colonial War Memorial Hospital, Suva, Fiji.

Secondary rhesus monkey kidney, human embryo kidney, human diploid (WI-38 and HEL 7 strains), and Bristol HeLa cells were used during this investigation. With the use of standard isolation procedures the HeLa tissue cultures were shown to contain mycoplasma agents. The laboratory procedures for tissue culture and virus isolation studies paralleled the methods described by the Medical Research Council (1965b).

Rhinoviruses isolated at 33° C. were recognized by their inability to grow at 37° C. in an alkaline medium, and lack of haemadsorption with human group O cells. Subsequently an acid stability test at *p*H 3 was performed (Dimmock and Tyrrell, 1962), and when calculated by the method of Reed and Muench (1938) a hundredfold or greater reduction in titre was taken as evidence of acid lability (Tyrrell and Chanock, 1963). If the rhinovirus was isolated in, or could be propagated in, rhesus monkey kidney cells it was designated as an M strain; otherwise it was classified as an H strain of rhinovirus. Isolates suspected of being herpes simplex virus were identified by neutralization with type-specific antiserum. Homologous rhinovirus neutralization was performed with serial fourfold dilutions of acute and convalescent serum inactivated at 56° C. for 30 minutes, starting at 1 in 8. Serum dilutions were incubated for one hour at room temperature with 50 to 100 50% tissue-culture infective doses ($TCID_{50}$) of homologous virus. Two WI-38 tubes were inoculated with 0.2 ml. of virus-serum mixture and were rolled at 33° C. Complete suppression of cytopathic effect after 10 days' incubation was used to determine the end-points.

Results

Virus Isolations

A total of 299 specimens from the chronic bronchitis patients and 109 specimens from the controls were obtained during the course of the study. Each specimen consisted of a nasal washing and throat swab; a sputum sample was also examined from the bronchitis patients. From the chronic bronchitis patients 237 specimens were taken during periods of quiescence or at more than 10 days after the onset of the acute respiratory symptoms. From the control subjects 88 specimens were examined when they were well. Of the 62 specimens obtained from the chronic bronchitis patients 10 days or less after the onset of an acute respiratory infection 56 had an acute exacerbation of bronchitis, and 38 of these were associated with upper respiratory symptoms. The 21 specimens from the control subjects were collected within six days of the onset of an acute upper respiratory illness.

Nineteen viruses were isolated during the course of the study, and 18 of these were rhinoviruses and one was a strain of herpes simplex isolated in human embryo kidney cells from the sputum of a patient 14 days after the onset of an acute exacerbation of bronchitis. No agents were isolated by means of the haemadsorption technique.

Table I shows the number of rhinoviruses isolated in relation to the clinical state of the chronic bronchitic and control subjects at the time of isolation. During quiescence five rhinoviruses were isolated from the patients and one from the control subjects in the absence of clinical illness, giving isolation rates of 2.1 and 1.1% for the patients and control subjects respectively. During acute exacerbations eight rhinoviruses were isolated from the patients and four were isolated from the control subjects at the time of an acute respiratory infection, giving an isolation rate of 14.3% for bronchitic subjects and 19% for control subjects. No viruses were isolated from the throat swabs or nasal washings collected more than six days after the onset of an acute respiratory infection except those unrelated to acute symptoms. The two rhinovirus strains isolated from the sputum were not recovered from nasal washings or throat swabs taken at the same time, and one of these was isolated 10 days after the onset of acute respiratory symptoms. Of 18 rhinovirus strains 13 were reisolated after storage for 4 to 12 months at $-70°$ C.

TABLE I.—*Number of Rhinoviruses Isolated in Chronic Bronchitic and Control Subjects in Relation to the Clinical State*

Subjects	No. of Specimens Tested	No. of Rhinoviruses Isolated	Percentage Isolated
Chronic bronchitic:			
Quiescent	237	5	2·1
Acute exacerbations of bronchitis ..	56	8	14·3
„ upper respiratory infections	6	0	—
Control:			
No illness	88	1	1·1
Acute respiratory infection	21	4	19·0

Neutralizing Antibody Titres

Table II summarizes the results of homologous neutralization tests carried out on six paired sera from subjects whose throat swabs or nasal washings yielded a rhinovirus. One of the patients from whom a rhinovirus was both isolated and reisolated in the quiescent state showed a high level of neutralizing antibody in the acute serum.

Acute	Convalescent	
<8	32	50
<8	16	100
<8	32	50
<8	8	100
<8	16	100
64	64	50

* Reciprocal values of titre given.

Clinical Picture

All the eight chronic bronchitic patients from whom a rhinovirus was isolated during an acute respiratory illness developed an acute exacerbation of bronchitis. This was characterized by increased production of sputum—purulent in six of the eight patients—increased wheeziness, shortness of breath, and cough. Five experienced substernal chest pain typical of tracheitis and six had mild rhinorrhoea. The control subjects, on the other hand, presented with an afebrile or febrile rhinorrhoea in association with a rhinovirus infection.

A clinical description of two of the acute illnesses associated with recovery of a rhinovirus from the chronic bronchitis patients is given.

Case 1.—A 62-year-old man experienced increased wheezing and coughing on 28 December 1964. Next day he developed rhinorrhoea, a mild sore throat, and substernal chest pain. His sputum increased in volume without becoming purulent, and he was more short of breath. A diagnosis of a common cold with acute tracheobronchitis was made. An H rhinovirus was isolated from his sputum obtained on 30 December. No virus was found in the throat swab or nasal washings taken at the same time. His symptoms gradually improved over the following week.

Case 2.—On 8 November 1964 a 50-year-old man developed malaise; he became more wheezy, and his sputum increased in volume and was purulent. When examined six days later he had improved slightly and there were no symptoms or signs of an upper respiratory infection. A diagnosis of acute exacerbation of bronchitis was made, and an M rhinovirus was isolated from a throat swab taken on 14 November 1964.

Discussion

Before rhinoviruses can be claimed to be a cause of acute exacerbations of bronchitis a modernized version of Koch's postulates must be fulfilled (Tyrrell, 1963).

Firstly, the respiratory secretions of a comparable group of patients and healthy subjects must be tested under similar conditions for the rhinoviruses. A comparison of the isolation rates of rhinoviruses of the chronic bronchitis patients and the control subjects during acute respiratory infections indicates that both groups are infected to a similar extent. The rhinovirus isolation rate of 2% for the chronic bronchitis patients in the quiescent phase and of 1% for the control subjects in the absence of clinical symptoms is in accord with previously published results from asymptomatic subjects (Hobson and Schild, 1960 ; Hamre and Procknow, 1961 ; Hamparian *et al.*, 1964). This indicates, firstly, that in both the chronic bronchitic and control groups the rhinoviruses are probably responsible for the disease produced, and, secondly, that the respiratory secretions of the chronic bronchitic subjects do not harbour rhinoviruses to any greater extent than normal subjects.

The results of the clinical studies show that in the bronchitic subjects rhinovirus infections result in acute exacerbations of bronchitis, while normal persons present a febrile or afebrile rhinorrhoea. These findings are in accord with the observations of Eadie *et al.* (1966), who reported that rhinovirus infections were more often associated with respiratory illnesses which affected the chest than with those which did not. These observations are supported by the findings of Cate *et al.* (1965), who, using a Collison atomizer, which gives a small-particle aerosol, showed experimentally that the lower respiratory tract of adults is quite sensitive to rhinovirus infection by producing, in volunteers, a tracheobronchitis with a low dose (16 to 11 $TCID_{50}$) of a rhinovirus.

The lower isolation rate of rhinovirus from the chronic bronchitis patients during acute exacerbations as compared with the findings of Eadie *et al.* (1966) is likely to be due to the earlier reporting of illness and the more frequent visitation of their patients. Of the 62 acute respiratory illnesses in the present study only six showed no evidence of involvement of the lower respiratory tract, as compared with 25 out of 75 reported by Eadie *et al.* (1966). This may be a reflection of a more advanced stage of the disease of the patients in the present study, but it is difficult to compare directly the ventilating function studies in the two groups. The report by Eadie *et al.* (1966) of the isolation of five rhinoviruses from the sputum, three of which were not recovered from a throat swab taken on the same occasion, is confirmed by the present study, where two rhinoviruses were isolated from the sputum but not from the throat swab or nasal washing, and indicates that attempts at sputum isolation are worth while.

The second modified Koch's postulate which it is desirable to fulfil is the demonstration of a rise in the titre of the homologous rhinovirus antibody during convalescence, indicating that infection was active at the time at which symptoms occurred and the virus isolation was made. In this study five out of six specimens tested showed a rise in titre of the homologous antibody in the convalescent specimen. The single exception occurred in a patient in the quiescent phase from whom a rhinovirus was isolated and subsequently reisolated from the throat swab. In this instance both the initial serum specimen and one taken four weeks later neutralized the homologous virus to a titre of 1 in 64. The possibilities are that this specimen was contaminated at the time of collection, that a subclinical reinfection occurred, or that the patient continued to excrete the virus for some time after infection—a situation which at present is only speculative.

These results indicate that in normal subjects rhinovirus infection gives rise to an afebrile or febrile coryzal syndrome while in chronic bronchitic patients an acute exacerbation of bronchitis is produced. It is likely that a more complete understanding of the nature of the agents responsible for the initiation of acute exacerbations will parallel the application of advances in techniques for the isolation of viruses from acute respiratory infections as a whole.

Summary

In a controlled prospective study employing virus isolation and homologous neutralizing antibody levels an association between rhinovirus infection and acute exacerbations of bronchitis in chronic bronchitic patients is described. Eight of 56 (14%) of such illnesses yielded rhinoviruses. The isolation of five rhinoviruses from 237 specimens (2.1%) from the same patients in the quiescent phase is in accord with previously published figures on the isolation rate of rhinoviruses from normal asymptomatic subjects.

The chronic bronchitis patients during rhinovirus infection present clinically with an acute exacerbation with or without an associated upper respiratory illness. This pattern of clinical illness is contrasted with a control group who presented a febrile or afebrile rhinorrhoea.

It is a pleasure to record my appreciation of the help received from Professor C. H. Stuart-Harris in all phases of this study and for the permission given to investigate patients under his care. I should like to thank the Chief Technician, Mr. J. Skelton, and the technical staffs of the Virus Research Laboratory, Lodge Moor Hospital, and of the department of medicine, the Royal Hospital, Sheffield, for their considerable part in this study ; in particular, Miss Lynda Bebbington for her excellent assistance at all times. I should also like to express my thanks to Dr. G. C. Schild, of the department of bacteriology, the University of Sheffield, for many helpful discussions, and to Dr. D. A. J. Tyrrell, of the Common Cold Research Unit, Salisbury, for continual advice and helpful comments on this paper.

Mycological and Clinical Evaluation of Griseofulvin for Chronic Onychomycosis

R. R. DAVIES,[*] M.SC., PH.D.; J. D. EVERALL,[†] M.R.C.P., M.R.C.S.; ELIZABETH HAMILTON,[*][‡] B.SC., PH.D.

Brit. med. J., 1967, **3**, 464–468

When griseofulvin became available in 1959 a critical evaluation of its use in chronic tinea of the nail was begun. Since then 122 patients have been treated with a standard dose[§] (0.5 g. t.d.s. for one month followed by 0.5 g. b.d.) for a minimum of six months and 74 for two years. As the trial progressed it became evident that a longer course of treatment was required than that suggested in earlier reports on the efficacy of the drug—namely, Williams *et al.* (1958) and Blank *et al.* (1959). It was therefore decided to treat for two years and to follow up the patient for a further year without treatment. Those failing to take the drug consistently throughout the lengthy period of treatment were transferred to an "intermittent-dose group."

Methods

At the patient's first visit numerous relevant clinical facts were recorded, and towards the end of the trial the blood and stool porphyrin levels were measured. All the nails of the hands and feet were examined mycologically and clinically, as were the soles, outer toe clefts, thumb crutches, and any other apparently affected site.

For the detailed mycological investigations parings were collected into sterile Petri dishes from all the nails, the clinically normal as well as the dystrophic, and skin scrapings were taken from the soles, webs, thumb crutches, and any other site that seemed to be infected. At least nine pieces of nail from each site were cultured—six in malt extract agar containing 40 μg. of chloramphenicol per ml. and 0.5 mg. of cycloheximide per ml. and three in peptone glucose agar containing 40 μg. of chloramphenicol per ml. Three or four small pieces of nail from each site were examined by direct microscopy in 30% potassium hydroxide (KOH). Skin scrapings were similarly investigated. The patients were thoroughly examined clinically at six-week intervals and the detailed mycological investigations were undertaken every six months.

When cultures were obtained the in-vitro sensitivities of the fungi were tested to investigate the possibility of their developing an increased resistance to the antibiotic during the course of treatment and to determine whether the sensitivity of the infecting organism to the antibiotic was reflected in the patient's response to therapy.

Results

When the trial was concluded 122 patients with mycologically proved onychomycosis had been treated for not less than six months. In 68 (56%) the infecting organism was *Trichophyton rubrum* (Castellani) Sabouraud, and in 22 (18%) it was *T. mentagrophytes* (Robin) Blanchard. From the nails of six patients both these species were isolated; and in 26, despite repeated attempts, no fungus was ever grown, though the presence of mycelium in KOH preparations was clear evidence of onychomycosis.

The number of patients treated with the standard dose or intermittent dose (defaulters) for various periods is shown in Table I.

TABLE I

Fungus	Dose	Months of Treatment				Months Followed	
		6	12	18	24	30	36
T. rubrum ..	Standard	47	41	38	32	23	15
	Intermittent	21	20	16	9	8	6
T. mentagrophytes	Standard	7	7	5	4	3	0
	Intermittent	15	13	11	11	7	7
T. rubrum + *T. mentagrophytes*	Standard	4	4	4	4	1	1
	Intermittent	2	2	1	1	1	1
No culture group	Standard	5	4	3	2	2	2
	Intermittent	21	18	12	11	8	4

Therapeutic Response in Patients with *T. rubrum* Infections

Response to treatment may be judged from two sets of criteria—by the clinical observation of dystrophy, and the mycological evidence of mycelium in KOH preparations or the isolation of dermatophyte fungi. When fungus is observed or is isolated from a dystrophic nail it is irrefutable evidence of infection; on the other hand the failure to discover fungus in the parings from a particular nail is not necessarily evidence that the whole nail is uninfected. However, where the nail has been repeatedly examined for fungus by two methods over a period of many months the possibility of missing an infection must be small, and in this respect it is noteworthy that during these studies dermatophyte fungi were found in clinically normal nails. Nail dystrophy, even in patients with some onychomycosis, is not necessarily due to fungal infection but might arise from a variety of causes. Since even a cosmetic improvement in the case of infected finger-nails is desirable, particularly in women, the clinical and more exact mycological findings are presented separately.

As *T. rubrum* was the commonest cause of onychomycosis in the patients studied, the response of those infected with this organism is described in detail; that of the other groups is briefly summarized.

Nail Infections Before Treatment

In 50 of the 68 patients onychomycosis involved both toe-nails and finger-nails, in 16 it was confined to the feet, and in 2 to the finger-nails alone. One patient, a 20-year-old male Chinese student, seemed exceptional in that all the finger-nails of his right hand were severely dystrophic, and though *T. rubrum* was isolated from each of the nails it was never obtained from any other site despite repeated attempts, and there were no clinical signs of infection elsewhere. He was the only patient with a nail infection who did not also have an infection of the smooth skin when first seen.

[‡] Now at 65 Greencourt Road, Petts Wood, Kent.

[§] The griseofulvin used was that first available; this has since been replaced by a variant of the drug of finer particle size.

The percentages of patients, with the number of finger-nails and toe-nails recorded from mycology or clinical observation as infected before treatment, are shown in Figs. 1 and 2. Of the patients presenting finger-nail infections 28 (58%) were judged to have dystrophy of all their finger-nails, though, mycologically, the maximum number infected in any patient was eight, and only four (6%) had as many as eight infected. The discrepancy between clinical observation and the mycological findings, though maintained throughout the trial, was less evident in toe-nail infections. Clinically, 48 (73%) of the patients were judged to have all their toe-nails infected, whereas mycologically in only 17 (26%) was this so.

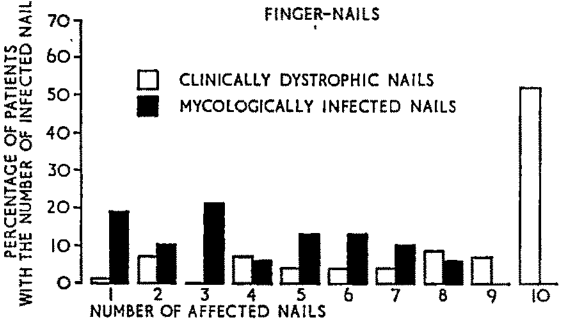

FIG. 1

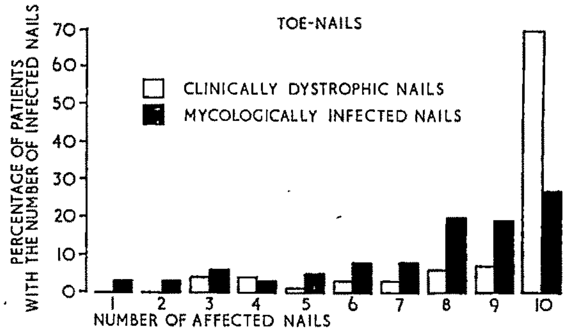

FIG. 2

FIG. 1.—Percentage of patients having one to ten finger-nails infected before treatment. FIG. 2.—Percentage of patients having one to ten toe-nails infected before treatment.

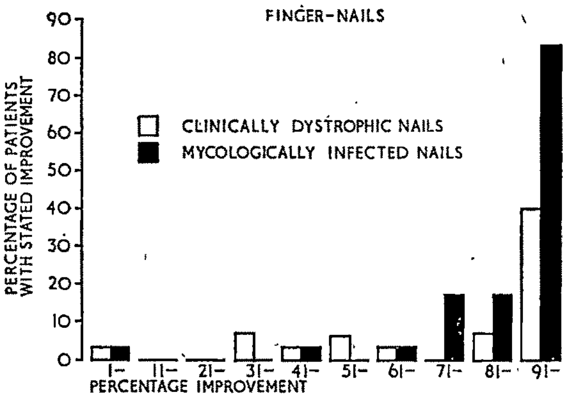

FIG. 3

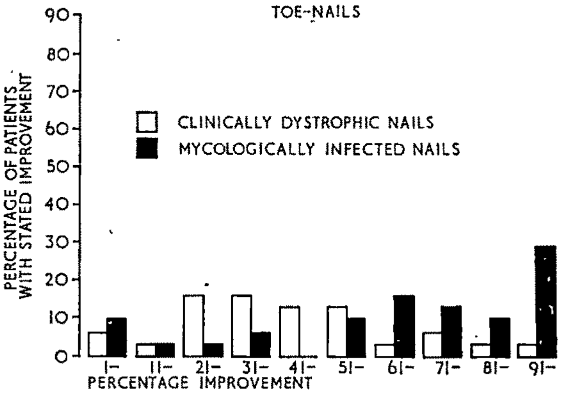

FIG. 4

FIG. 3.—Patients with *T. rubrum* infection of finger-nails treated with a standard dose of griseofulvin for two years; percentage showing improvement, which for each patient was calculated as a percentage of the maximum of nails infected. FIG. 4.—Patients with *T. rubrum* infection of toe-nails treated with a standard dose of griseofulvin for two years; percentage showing improvement, which for each patient was calculated as a percentage of the maximum of nails infected.

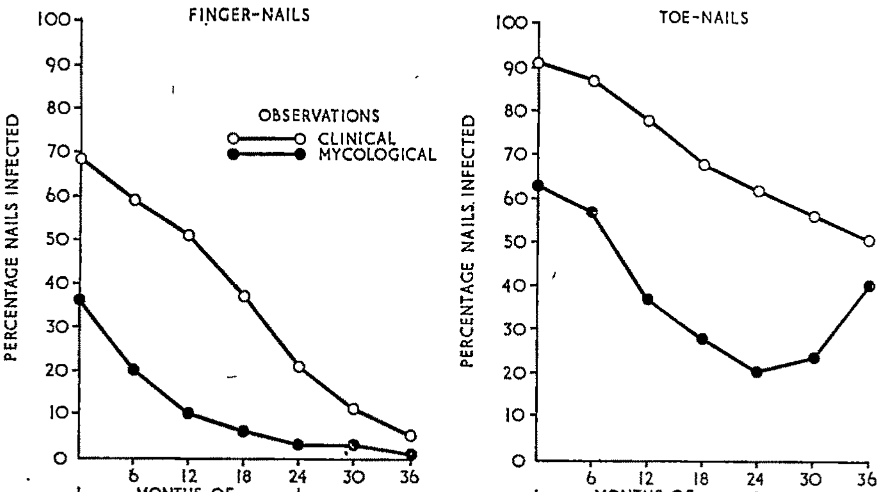

FIG. 5.—Percentage of infected nails in patients with *T. rubrum* infections treated with a standard dose of griseofulvin for 24 months and followed for another 12 months without treatment.

Therapeutic Response to Standard Dose

Response to treatment (Figs. 3 and 4) is given as the percentage of patients showing an improvement, which for each subject has been calculated as a percentage of the maximum number of nails infected. After 24 months' treatment clinical cures were recorded in 12 (40%) patients with finger-nail infections; mycologically, 24 (80%) were cured. With regard to toe-nail infections, while only 1 patient (3%) was thought to be clinically cured, the mycological evidence showed that in 9 (29%) patients cure was effected.

After 24 months, during which time each patient had taken 1 g. of griseofulvin daily for 23 months, treatment was stopped and the patients were kept under observation for another year. It must here be emphasized that in the trial of a treatment "for a relatively rare" condition it takes many months to collect patients, and when after six years we decided to conclude the trial, though 74 patients had been treated for two years, only 53 had been followed for six months after treatment and 36 for the full year. Since the number treated and followed diminished steadily between 6 and 36 months, to determine the effect of treatment and its cessation in a group of patients the percentage of infected nails at each of the different time intervals is shown in Fig. 5.

On both clinical and mycological criteria the numbers of infected finger-nails decrease and show no evidence of relapse during and after treatment. With toe-nail infections the clinical observations reveal a steady improvement throughout, from 91% down to 62% of toe-nails infected at the end of treatment, down to 51% of the nails infected after a further year without treatment. The mycological evidence shows improvement from 63% of toe-nails infected before treatment down to 20% infected after two years' treatment. Six months after treatment was stopped a small rise to 23% of infected nails was recorded, but within a year of stopping treatment 40% of the nails were found to be infected, showing clear mycological evidence of relapse not apparent to the clinician.

Thumb Crutch and Outer Toe Web Infections

During the course of the trial it became apparent that in some patients outer toe web infections were persistent. The percentage of patients having both, one, or no thumb crutches infected and both, one, or no outer toe webs infected, as shown by mycological evidence after different periods of treatment and during the follow-up periods, is illustrated in Fig. 6.

After 12 months' treatment both thumb crutches were clear in over 75% of the patients, after two years 95% of the patients had clear thumb crutches, and there is no evidence of relapse during the year without treatment. With outer toe web infections, however, only 53% of the patients had clear toe webs after two years' treatment, 28% had both webs infected, and 19% had one web infected. A year after the cessation of treatment the proportion of patients with clear toe webs had fallen to 45%, and the number of patients with both their outer toe webs infected had risen 45%. There is therefore a relapse in the smooth-skin infections of the feet which parallels that observed with the toe-nails.

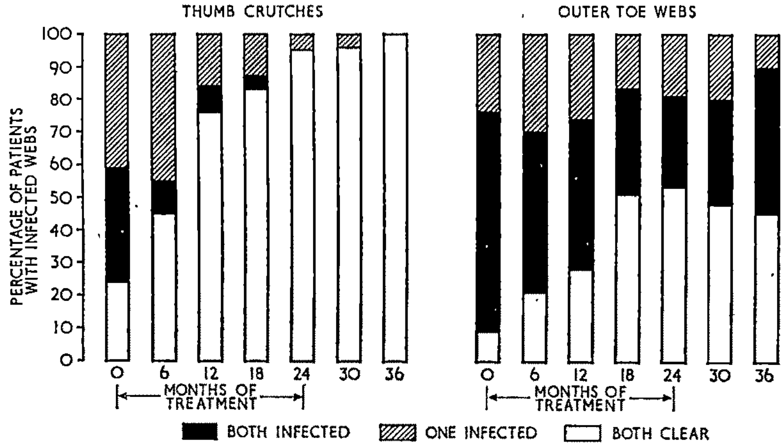

FIG. 6.—Percentage of patients with thumb crutches and outer toe-webs infected by *T. rubrum* as shown by mycological evidence after different periods of therapy with a standard dose of griseofulvin and during a follow-up year without treatment.

Response to Intermittent Griseofulvin Treatment

This smaller group of patients comprised those who were prescribed the standard dose but omitted to take the drug for periods varying from weeks to months during the lengthy period of treatment. The percentage of nails found infected according to clinical and mycological criteria are given in Table II.

TABLE II.—*T. rubrum Response to Intermittent Treatment*

Observations	Months Treated and Followed						
	0	6	12	18	24	30	36
	Percentage of Toe-Nails Infected						
Clinical	76	52	69	64	68	56	64
Mycological	56	43	36	38	38	26	63
	Percentage of Finger-Nails Infected						
Clinical	66	44	25	16	33	14	13
Mycological	43	15	11	14	4	0	1

Clinically, no patient with a toe-nail infection was cured, but 5 out of 10 defaulting patients were cured of their finger-nail infections. Mycologically, three out of eight patients examined after two years' treatment were cleared of toe-nail infections, but one relapsed and had four nails infected after six months without treatment. Another of these patients, who had 10 toe-nails mycologically infected at 12 months, had three infected at 24 months, one at 30 months, and 10 at 36 months. Both these cases presented mycological evidence of relapse in toe-nail infections when treatment was stopped. Mycologically, among five patients with finger-nail infections who were examined after 24 months two had infected nails, but one cleared during the follow-up period and the other was 86% improved.

T. mentagrophytes Infections and Response to Treatment

Of the 22 patients with nail infections due to this fungus only seven did not at some time default in taking the prescribed treatment, and none of these was followed for more than 30 months. As seven of the defaulters were followed for a year after treatment was stopped all the patients with infection due to this fungus are best considered together.

Of the 12 patients treated for two years with finger-nail infections six showed a clinical cure and 10 (83%) were mycologically clear. Thirteen patients with *T. mentagrophytes* infections of their toe-nails were treated for two years, and though no clinical cure was recorded six (46%) were mycologically clear.

The percentage of nails found infected after different periods of treatment is given in Table III. The mycological results are biased in that among 13 patients three with toe-nail infections and one with a finger-nail infection grew worse during the period of treament. The mycological observations on patients with *T. rubrum* infections showed that no patient taking the standard dose of griseofulvin became worse, and among the *T. rubrum*-infected patients treated with an intermittent dose only one patient's toe-nails failed to show improvement.

TABLE III.—*T. mentagrophytes Response to Intermittent Treatment*

Observations	Months Treated and Followed						
	0	6	12	18	24	30	36
	Percentage of Toe-Nails Infected						
Clinical	88·5	75	70	66·5	36	56	49
Mycological	25	22	27	14·5	18	14	13
	Percentage of Finger-Nails Infected						
Clinical	54	28	32	24	22	24	23
Mycological	19	3	12	3	5	13	10

Mixed *T. rubrum* and *T. mentagrophytes* Infections

Six patients had nails infected with both *T. rubrum* and *T. mentagrophytes*. From the nails of another three patients *T. rubrum* was isolated consistently at examinations during the course of treatment, and during the examination at the cessation of treatment *T. mentagrophytes* was found. There were also three patients in whom one of the species of *Trichophyton* was isolated from the nails and the other from the skin.

Before treatment the frequency with which *T. rubrum* was isolated relative to *T. mentagrophytes* from the nails of these patients was 22 to 9; after griseofulvin for a year or more 16 isolates of *T. mentagrophytes* were obtained to 14 of *T. rubrum*. It would therefore appear that *T. mentagrophytes* in nails is less susceptible to griseofulvin than is *T. rubrum*.

Onychomycosis—Fungus Unknown

In 26 patients treated for over six months, while no fungus was isolated, a diagnosis of onychomycosis was confirmed when mycelium was observed in KOH preparations. Of these patients 13 were treated for two years—two with the standard dose and 11 with intermittent dosage—and six were followed for a year after treatment. Despite repeated attempts no fungus was isolated from the nails of these patients. The percentage of nails infected according to clinical and mycological criteria during the course of treatment and follow-up periods is given in Table IV.

TABLE IV.—*Percentage of Toe-nails and Finger-nails Infected with Fungus not Isolated*

Observations	Months Treated and Followed						
	0	6	12	18	24	30	36
				Toe-nails			
Clinical	92	58	70	61	59	54	60
Mycological	30	11	7	15	6	8	0
				Finger-nails			
Clinical	53	59	44	44	17·5	16	32
Mycological	17	14	3	1	1	1	0

The trial described was terminated in 1964. In October 1966 a questionary was sent to 74 patients who had been treated for two years. They were asked if their finger-nails and toe-nails were better or worse, how many were affected, whether they had any irritation or peeling or trouble with the skin of the hands or feet, and whether or not they had consulted a doctor and received treatment for any skin or nail infection.

Only 27 patients returned their forms correctly completed. Of these nine regarded their toe-nail infections as cured, but six of these were known to have had infected toe-nails when they were last seen. Among 18 patients reporting infected toe-nails five recorded a greater number of infected nails than when they were last seen. Another four stated that all their toe-nails were infected, as shown at their last visit to the clinic. From the patients' own descriptions of the state of their toe-nails nine seemed to be unchanged.

Only one patient reported a relapsed finger-nail infection, and he had shown a poor response to treatment throughout the course. Three patients reported peeling skin, four recorded irritation, and four had consulted a doctor.

Toxicity

No patient complained of serious subjective side-effects, but a few reported headaches, which ceased either spontaneously or when the tablets were taken with meals. No change in the red and white blood cell counts was observed in patients under treatment.

Griseofulvin when given to rats in large doses intravenously or intraperitoneally has been reported by Paget and Walpole (1958) to have colchicine-like effects on the seminal epithelium and bone marrow. With high dosage in mice, toxic liver damage occurs (De Matteis and Rimington, 1963), and prolonged intake of griseofulvin leads to the development of hepatoma in the enlarged liver (Hurst and Paget, 1963). Blood and stool porphyrin levels were determined in 84 of the patients in the present trial, and the results have been reported by Rimington *et al.* (1963). Faecal porphyrins were raised in 21 of 50 patients receiving treatment, and in 51 patients in whom erythrocyte porphyrins were determined normal maximum values were exceeded in 20. However, in four out of six patients with onychomycosis who had not been treated with griseofulvin total faecal porphyrins exceeded the normal, and in two blood coproporphyrin levels were slightly raised. Conventional liver-function tests on 10 patients with raised and 10 with normal porphyrin excretion showed no evidence of abnormality.

In vitro Sensitivity of *T. rubrum* and *T. mentagrophytes* to Griseofulvin

Griseofulvin stock solutions in 50% acetone were sterilized by Seitz filtration, and serial dilutions were made in Sabouraud's glucose peptone agar. The concentrations employed to determine the minimum inhibitory concentrations for strains of *T. rubrum* ranged from 0.75 to 4 μg./ml. in 0.25-μg. steps. The inoculum was taken from a freshly grown colony, which when it had attained a diameter of 2 cm. was scraped from the medium, added to 5 ml. of sterile distilled water in a tissue grinder, and after grinding transferred to a sterile container. Each of a series of plates containing griseofulvin, together with control plates, were then inoculated with three 0.02-ml. drops of the inoculum in random order. The cultures were incubated at 25° C. and read after 10 days, and the next highest concentration to that on which growth was recorded was taken as the minimum inhibitory concentration. A total of 57 cultures obtained from patients before treatment and 186 from patients treated for a year or more were screened. The group of pretreatment isolates had a mean M.I.C. of 1.93 μg./ml. (S.D. 0.54), the group from treated patients a mean M.I.C. of 2.17 μg./ml. (S.D. 0.54). Student's *t* test showed no significant difference between the means of the two groups at the 0.1 level. It may be concluded that in patients infected with *T. rubrum* failure to respond to treatment is not due to the fungus becoming resistant to the antibiotic.

The griseofulvin concentrations used to determine the minimum inhibitory concentrations for *T. mentagrophytes* ranged from 2.5 to 16.5 μg./ml. in 1-μg. steps, and cultures were read after seven days' incubation. The 19 isolates obtained from untreated patients had a mean M.I.C. of 4.8 μg./ml. (S.D. 4.68); 98 cultures from patients treated for a year or more had a mean M.I.C. of 7.17 μg./ml. (S.D. 9.37). Student's *t* test showed no significant difference between the means of the two groups at the 0.2 level. In patients infected with *T. mentagrophytes* failure to respond to therapy is not due to the fungus becoming adapted to the antibiotic.

Discussion and Conclusions

In 1961 Ainsworth reported, "More than a hundred papers have been published to show that 1 g. daily of griseofulvin taken orally effectively controls infection in man by diverse dermatophytes in all five continents." This has not been our experience in the study described. Most reports have been a clinician's account of his observations on a small number of patients over a brief period, and, apart from the investigation by Stevenson and Djavahiszwili (1961), even where a clinical diagnosis was confirmed mycologically no consistent mycological investigations appear to have been undertaken.

Alone in the present study have all the nails been repeatedly examined mycologically at regular intervals during and after treatment whether they were dystrophic or not. Stevenson and Djavahiszwili (1961), with 0.5 g. of griseofulvin thrice daily, found that 5 out of 14 patients still had *T. rubrum*-infected toe-nails after 15 months' treatment. The two-year treatment in our trial is the longest one described. Both 1 g. of griseofulvin daily for two years and 1.5 g. daily for 15 months have been inadequate for the elimination of toe-nail infections due to *T. rubrum*. A small group of patients not shown in the results described gave a better response when treated with 1.5 g of griseofulvin daily, but some patients naturally respond better than others. In the follow-up the mycological evidence described showed relapse in toe-nails infected with *T. rubrum* before it was apparent to the clinician (Fig. 5). Among patients who completed questionaries two years later 18 recorded infected toe-nails and 5 (28%) reported a greater number infected than when they were last seen.

Finger-nail infections showed a better response than toe-nails on both mycological and clinical criteria (Fig. 5), and there was no evidence of relapse during the follow-up. Among patients completing questionaries only one described a relapsed finger-nail infection, and he had shown little response to treatment. From the mycological evidence of thumb crutch and outer toe web infections due to *T. rubrum,* the response of smooth-skin infections parallels that of the nails. After two years 95% of the patients had clear thumb crutches, and there is no evidence of relapse during the year without treatment, whereas with outer toe web infections only 53% of the patients had clear toe webs after two years' treatment, and this fell to 45% during the year without treatment.

In no case could a patient's failure to respond to therapy be ascribed to the fungus becoming insensitive to the drug. The rate of growth of finger-nails was unrelated to therapeutic response, as also was the griseofulvin serum levels attained in a limited number of patients.

Mycological observation on patients with nails infected with *T. mentagrophytes* showed that some became worse during the course of treatment; this was not observed in patients with *T. rubrum* infections, and only one patient with a *T. rubrum* infection was not improved. In patients whose nails were infected with both these fungi the frequency with which *T. mentagrophytes* was isolated relative to *T. rubrum* increased during the course of treatment. It may be concluded, therefore, that in nails *T. mentagrophytes* is less likely to be inhibited by oral griseofulvin than *T. rubrum*; in-vitro tests showed that *T. rubrum* has a mean M.I.C. of 2 µg./ml., whereas that for *T. mentagrophytes* was 6.25 µg./ml.

The fact that toe-nail and outer toe web infections did not respond as well as finger-nail and thumb crutch infections may be due to a variety of causes. Gentles (1958) and Gentles *et al.* (1959) have shown that griseofulvin is incorporated in hair, where it presents a barrier to fungal penetration. There seems to be no record of griseofulvin having been recovered from human nails, or of the amounts in finger-nails versus toe-nails. The moisture content of the skin in the toe webs must, however, be higher than that of the thumb crutch, and the effect of sweat in leaching out griseofulvin from the tissues cannot be overlooked. The warm moist feet present a better ecological niche for fungal colonization than the hands, which tend to be drier and cooler, and this alone may account for early relapse in infections of the feet after the cessation of treatment when fungus has not been completely eradicated by the fungistatic antibiotic.

It has been found (Davies, in preparation) that finger-nail is more slowly hydrolysed by KOH than is toe-nail, and appears to be a more compact tissue into which griseofulvin may be incorporated as a barrier to fungal penetration. The fingers have a better blood supply than the feet, and finger-nails may consequently receive more griseofulvin, though while the finger-nails grow more quickly than toe-nails it does not necessarily follow that the concentration of griseofulvin in the tissue is higher. What must be concluded, however, is that insufficient griseofulvin is incorporated in toe-nails with the dosages so far tried. Though the drug has a low toxicity with the dose regimen prescribed in the present study, it has affected blood and stool porphyrin levels. In high dosage it has colchicine-like effects on nuclear division, and any long-term toxic effect must await the test of time. Griseofulvin, however, must remain the treatment of choice for finger-nail infections, especially in women, but should never be prescribed for smooth skin infections, which are resolved with topical treatments, and its use in toe-nail infection is justifiable only when the patient has severe discomfort. Whether dosage with the new finer-particle-sized variant of the drug can be increased sufficiently to cure the chronic toe-nail infection without any deleterious effect remains to be seen.

Summary

Griseofulvin by mouth was used to treat 122 patients with chronic fungal infections of their nails for a minimum of six months; 74 received the drug continuously for two years, and 36 were followed for another year after the cessation of treatment to study relapse. Patients were assessed clinically at six-week intervals and a detailed mycological investigation of all their nails, thumb crutches, and outer toe webs was undertaken before treatment and at six-monthly intervals thereafter. All patients were prescribed 0.5 g. of griseofulvin t.d.s. for the first month, followed by 0.5 g. b.d.; those failing to take the drug consistently were transferred to an intermittent-dose group. Treatment was found to be less effective in infections of the toe-nails and outer toe webs than in those of the finger-nails and thumb crutches, which showed a good response; a significant number of toe-nails and outer toe webs relapsed after treatment was stopped.

The response of patients with infections due to *Trichophyton rubrum* is described in detail, as they comprised the largest group; that of patients infected with *T. mentagrophytes*, mixed infections due to both these fungi and of patients with chronic onychomycosis but from whom no fungus was isolated are only briefly described.

Response to therapy in nails infected with *T. mentagrophytes* is less favourable than in those infected with *T. rubrum,* and in nails infected with both these fungi *T. mentagrophytes* becomes dominant during treatment. In-vitro tests showed that *T. mentagrophytes* was less sensitive to griseofulvin than *T. rubrum.* Failure to respond to treatment could not be correlated with the sensitivity of the fungus isolated from any patient, and there was no evidence of the fungi developing an increased resistance to griseofulvin.

Observations on toxicity are discussed, and it is concluded that while griseofulvin is the treatment of choice for chronic finger-nail infections it should not be prescribed for smooth-skin infections, which are resolved with topical treatments, and its use in toe-nail infections is justifiable only when the patient has severe discomfort.

We are indebted to Miss M. J. Denny and Miss C. Howard for technical assistance; to the Imperial Chemical Industries Ltd. and the Govenors of St. Mary's Hospital for generous financial assistance; and to Mr. E. Hyde, of I.C.I., for his help with punched-card data recording and retrieval.

Importance of Dietary Calcium in the Definition of Hypercalciuria

M. PEACOCK,* M.B., CH.B.; A. HODGKINSON,* D.SC., F.R.I.C.; B. E. C. NORDIN,* M.D., PH.D., M.R.C.P.

Brit. med. J., 1967, 3, 469–471

The relation between a high urinary calcium and renal stone disease was first noted by Flocks in 1939, but the recognition of "idiopathic hypercalciuria" as an entity in its own right dates from 1953, when the condition was described by Albright, Henneman, Benedict, and Forbes. These workers defined a syndrome in which a high urinary calcium was associated with normocalcaemia, a tendency to hypophosphataemia, and renal stone formation, and this syndrome has since been recognized by many other workers in the field (Henneman, Benedict, Forbes, and Dudley, 1958; Harrison, 1959; Litin, Diessner, and Keating, 1961; Parfitt, Higgins, Nassim, Collins, and Hilb, 1964; Edwards and Hodgkinson, 1965).

The cause of the high urinary calcium has never been established. The original workers suggested that it was a renal tubular disorder possibly associated with an ascending pyelonephritis (Albright *et al.*, 1953), but this has never been confirmed. Other workers have subsequently observed a reduced faecal excretion of calcium in idiopathic hypercalciuria (Henneman *et al.*, 1958; Harrison, 1959; Jackson and Dancaster, 1959; Hodgkinson, 1961). Whether this is the cause or the result of the condition is unknown, but Jackson and Dancaster (1959) suggested that the hyperabsorption was secondary to the hypercalciuria. Attempts to lower the urinary calcium by restricting calcium intake have been successful in some cases (Hennemann *et al.*, 1958; Harrison, 1959; Gill and Bartter, 1961) but not in others (Jackson and Dancaster, 1959; Edwards and Hodgkinson, 1965). This discrepancy may signify that some of the patients studied have tubular hypercalciuria or that the restriction of dietary calcium has been inadequate. Dent and Watson (1965), for instance, described the case of a man with hypercalciuria whose urinary calcium was finally reduced to normal when he was instructed to drink distilled water in addition to having a very strict low-calcium diet.

In studying this problem further we have encountered difficulty in defining exactly what is meant by hypercalciuria. Though the definition of Hodgkinson and Pyrah (1958)—a urinary calcium over 250 mg. in females and 300 mg. in males—has been widely adopted and proved useful in practice, we have seen many patients whose urinary calcium on a free diet varies substantially from one day to another. Such patients would be defined as "hypercalciuric" on one occasion and as "normocalciuric" on another. We have therefore found it necessary to examine in more detail the relation between dietary and urinary calcium in an attempt to define more rigorously what is meant by hypercalciuria and to understand its nature.

The present paper deals with the relation between dietary and urinary calcium in normal and stone-forming subjects and presents evidence to suggest that hyperabsorption is more likely to be the cause than the result of idiopathic hypercalciuria.

Clinical Material and Methods

Stone-forming Patients.—The patients consisted of 31 idiopathic male stone-formers, and 21 idiopathic female stone-formers, most of them having been "hypercalciuric" at one time or another according to the definition given above. They were admitted to a metabolic ward and studied on two known calcium intakes: a low intake of 2–5 mg./kg./day and a high intake of 15–20 mg./kg./day. The duration of study on each intake was variable, but was not less than five days. Urine was collected 24-hourly for calcium estimation, and the calcium excretion was expressed as the average of the last three days on a particular regimen.

Controls.—These were of two kinds: observations of our own and data collected from the literature. Our own non-stone cases comprise all the subjects studied by us at two calcium intakes who had no disease involving or affecting calcium metabolism other than simple ageing. There are 13 males in this category and 21 females. In addition, we have collected from the literature data on 31 normal male adults in whom urinary calcium data were available at two intake levels (Steggerda and Mitchell, 1941; Malm, 1958; Jackson and Dancaster, 1959; Clarkson, McDonald, and de Wardener, 1966). Our own control data fell within the same range as the normal data extracted from the literature.

Diets.—The patients were first studied on a low-calcium diet. This was followed by a high-calcium diet which consisted of the previous low-calcium diet supplemented with milk.

Biochemical Methods.—Various biochemical methods were used for the measurement of urinary calcium since the data were collected over a period of 12 years. The main methods were oxalate precipitation followed by permanganate titration, flame photometry by means of the Eppendorf flame photometer, or colorimetry with murexide or cresolphthalein complexone (Technicon Instruments Ltd. Method N 3). There is satisfactory agreement between urine calcium values obtained by these four methods.

Results

The relation between urinary and dietary calcium in the male subjects is shown in Fig. 1. The shaded area represents the normal range as established by us previously from observations in the literature (Nordin and Smith, 1965). It is apparent that in the great majority of stone-formers the urinary calcium on

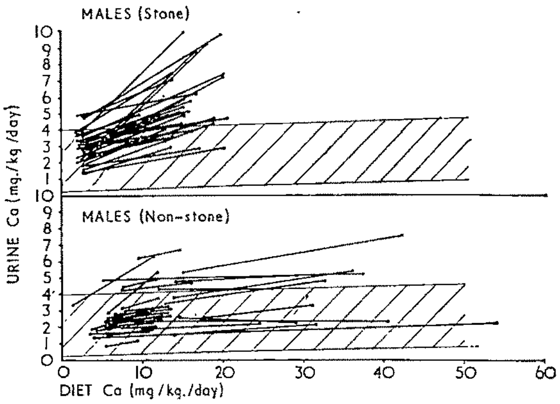

FIG. 1.—Relation between urinary and dietary calcium in male stone-formers (top) and non-stone-formers (below). The shaded area represents the approximate normal range.

---

* Medical Research Council Mineral Metabolism Unit, the General Infirmary, Leeds 1.

a low-calcium diet falls within the normal range. However, when the dietary intake is raised, urinary calcium rises steeply in most cases until at the higher intakes it is generally above or at the upper limit of the normal range. By contrast, the great majority of the male controls fall within or only slightly above the normal range, and, in particular, do not show the steep slope of urinary on dietary calcium which is a feature of the stone-formers.

The corresponding data for females are shown in Fig. 2. In the women there is very much less difference between stone-formers and controls than in the men. A few stone-forming cases lie above the suggested normal range, but the same is true of three of the controls. Some of the stone-forming cases have rather steeper slopes of urinary on dietary calcium than are seen in the control series, but most are within the normal range in this respect.

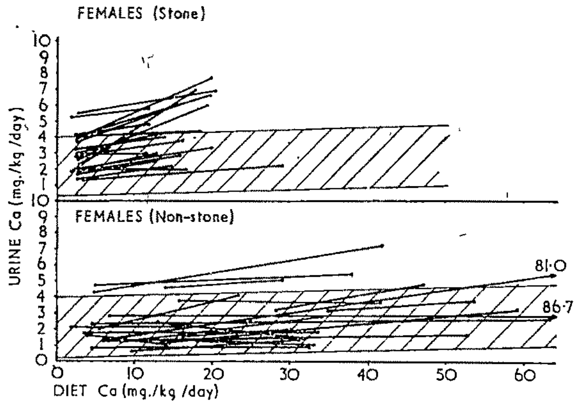

FIG. 2.—Relation between urinary and dietary calcium in female stone-formers (top) and non-stone-formers (below). The shaded area represents the approximate normal range.

These data can also be analysed in other ways. Firstly, the relation between urinary and dietary calcium can be expressed as a slope which denotes the change in urinary calcium for each unit change in dietary calcium. Secondly, this slope of urinary calcium on diet can be extrapolated back to a theoretical zero intake and the result expressed as the intercept of the slope on the urinary calcium axis. The data shown in Figs. 1 and 2 are expressed in these two ways in Figs. 3 and 4 and in the Table.

Relation of Urinary to Dietary Calcium in Stone-forming and Non-stone-forming Individuals

	Non-stone Cases			Stone Cases			*t*	P
	No. of Cases	Mean	S.E.	No. of Cases	Mean	S.E.		
	Mean regression coefficients of urinary on dietary calcium							
Males	44	0·074	0·012	31	0·199	0·020	5·4	<0·001
Females	21	0·029	0·008	21	0·105	0·019	3·8	<0·001
	Mean values of theoretical minimal urinary calcium (mg./kg./day)							
Males	44	2·31	0·19	31	2·37	0·16	0·24	>0·1
Females	21	1·95	0·28	21	2·53	0·22	1·66	>0·1

Fig. 3 shows the slope of urinary on dietary calcium in the stone-forming and non-stone-forming males and females. It is apparent that this slope has a gradient of less than 0.1 in the great majority of control males (mean 0.074) and of more than 0.1 in nearly all the stone-forming males (mean 0.199). This difference is highly significant (see Table). In the females the mean slope in the stone-formers is 0.105 and in the controls 0.029. This difference is also highly significant.

The theoretical urinary calcium values at zero calcium intake are shown in Fig. 4. The mean in the male non-stone-forming cases is 2.31 and in the stone-formers 2.37 mg./kg./day. In the females the corresponding values are 1.95 and 2.53 mg./kg./day. These differences are not significant (see Table).

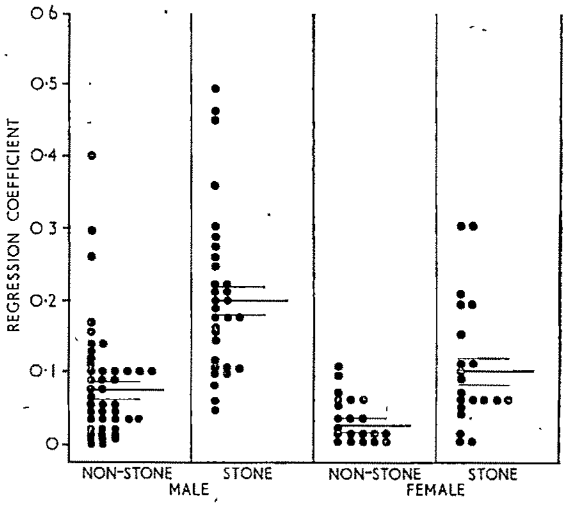

FIG. 3.—Regression coefficients of urinary on dietary calcium in male and female stone-formers compared with non-stone-forming individuals. The horizontal bars represent the means ± one standard error.

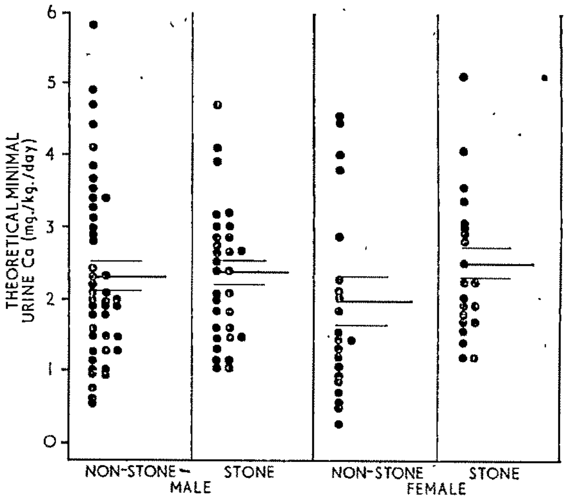

FIG. 4.—Theoretical minimal urinary calcium at zero calcium intake in male and female stone-forming and non-stone-forming individuals. The horizontal bars represent the means ± one standard error.

Discussion

Our data show that hypercalciuria should only be defined in relation to dietary calcium intake. Though the definition of hypercalciuria proposed by Hodgkinson and Pyrah (1958) has been and remains a useful guide, the fact that urinary and dietary calcium are closely related in stone-forming subjects indicates the need to define the dietary intake whenever the urinary calcium is examined in detail. Measurement of urinary calcium at two levels of intake enables patients to be classified into three different categories. Firstly, those in whom urinary calcium is high on a high intake but falls into the normal range on a low intake; these probably represent the majority of the male cases of so-called "idiopathic hypercalciuria." Secondly, those in whom urinary calcium is high on a high intake but remains high on a low intake; this is the general picture with sustained hypercalcaemia, but in the absence of hypercalcaemia probably denotes reduced tubular reabsorption of calcium. Thirdly, those patients whose urinary calcium falls within the normal range at high- and low-calcium intakes and who from this point of view are entirely normal.

We find that the majority of cases of idiopathic hypercalciuria, particularly the males, fall into the first category. Their urinary calcium at very low intakes is normal—that is, less than 4 mg./kg./day—but it rises more steeply than normal as intake is raised, and therefore tends to be high on the average dietary calcium of this country (about 20 mg./kg./day). This close relation between dietary and urinary calcium suggests, but does not prove, that the hypercalciuria is absorptive in origin as Caniggia, Gennari, and Cesari (1965) believe. It is possible to conceive of a renal "leak" which operates only at high intakes of calcium, but this seems to us an improbable explanation of our results.

In women the picture is much the same, though only a minority of the female stone-formers (6 out of 21) have a slope of urinary on dietary calcium above the upper limit of non-stone controls. The difference between the mean slopes is highly significant, whereas the theoretical urine calcium at zero intake does not differ as between the two groups.

It would be of the greatest interest to know whether the hypercalciuria of renal stone disease has the same basis as the hypercalciuria seen in a proportion of apparently normal individuals. It has repeatedly been noted that the urinary calcium of normal subjects is distributed asymmetrically in that there is a "tail" of high values in any normal population, which has been variously estimated at 10–14% of the total (Hodgkinson and Pyrah, 1958). This is probably not attributable to differences in intake, since it is still apparent when intake is taken into account (Knapp, 1947; Watson and Dale, 1966). We have therefore recalculated the data of Knapp (1947) to make them comparable with our own (Fig. 5), and found that the hypercalciuria of her normal individuals is essentially the same as that of our stone-formers. Examination of the "upper limit" in Fig. 5 shows that Knapp's series of 606 subjects must have included a small proportion of "hypercalciuric" individuals in whom the slope of urinary on dietary calcium was much steeper than in the majority. This "hypercalciuria" is not apparent at very low calcium intakes where the distribution of urinary calcium is apparently normal, but as the intake is raised the upper limit rises steeply in much the same way as in our hypercalciuric stone-formers shown in Figs. 1 and 2. We take this to mean that the basis of "idiopathic" hypercalciuria in stone-forming individuals is probably the same as that in normal controls—that is, absorptive in origin. This implies that idiopathic stone-formers are largely drawn from that segment of the population in whom absorption, and therefore urinary excretion of calcium, is above the average.

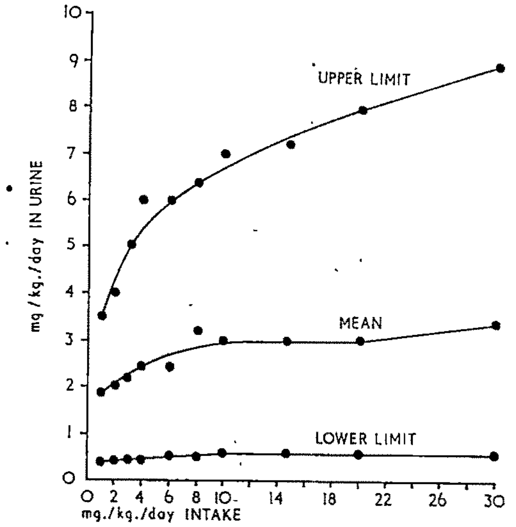

FIG. 5.—Relation between urinary and dietary calcium in normal individuals calculated from the data of Knapp (1947).

Summary

Urinary calcium was determined at two known levels of intake in 31 male and 21 female idiopathic stone-formers, and the results are compared with 13 males and 21 females with no history of stone. In addition, comparable data collected from the literature on 31 normal male adults are included.

At low-calcium intakes there was little difference in the urinary calcium excretion of stone-forming and non-stone-forming individuals, but as the intake was raised the urinary calcium rose more steeply in the stone-formers than in the controls. "Hypercalciuria" was therefore detectable only at moderately high calcium intakes, the characteristic feature of this syndrome being a steep slope of urinary on dietary calcium. This relation of urinary to dietary calcium is similar to that reported by Knapp (1947) in a small proportion of normal individuals.

It is concluded that "hypercalciuria" can only be defined in relation to calcium intake; that "idiopathic hypercalciuria" is generally attributable to an increased calcium absorption; and that the hypercalciuria of idiopathic stone disease is probably of the same nature as that seen in a small proportion of normal individuals.

Renal Function after Leptospirosis

B. SIMPSON,* M.A., M.B., M.R.C.P.ED.; A. T. COOK,† M.B., M.R.C.P.; A. H. DIMOND,‡ M.A., M.B., M.R.C.P.

Brit. med. J., 1967, **3**, 472–473

It is generally assumed that a patient who survives an attack of leptospirosis is left with normal kidneys (Van Thiel, 1948; Gsell, 1952; Ross Russell, 1959), but no long-term follow-up study has been published and certain facts suggest the need for such an investigation. Firstly, the frequency of renal damage in this disease is illustrated by the reports of Penna *et al.* (1963) and de Brito *et al.* (1965) in Brazil; they obtained renal biopsy specimens between the eleventh and forty-fifth days of the illness, and even in patients with minimal impairment of renal function they demonstrated infiltration of the interstitial tissue with lymphocytes and histiocytes, tubular damage, focal thickening of the glomerular basement membrane, and objects resembling leptospirae. Further, leptospiruria is not uncommon and may persist for as long as 11 months (Johnson, 1950); indeed, Spînu *et al.* (1962), who studied an epidemic outbreak of leptospirosis in Vietnam, concluded that in certain circumstances human excreters might be the source of spread. It thus seems possible that leptospirosis might cause chronic renal damage and impairment of renal function, and this paper describes an investigation into this aspect.

Present Investigation

Our patients were soldiers who contracted leptospirosis in South-East Asia, where the disease is an important military problem and caused 333 admissions to hospital in 1954–5 (Levis, 1957). Renal damage provides the main problem in management, though since the introduction of rational conservative therapy for uraemia the main cause of death in the few fatal cases (less than 2% of patients) has been haemorrhage (Trimble, 1957). Thirty serotypes have been incriminated in this group (Alexander *et al.*, 1957), including *Leptospira icterohaemorrhagiae* and *L. canicola,* and there is no correlation between the serotype responsible for the illness and the severity of the renal lesion, jaundice, or meningitis. This finding is in accord with the experience of Continental workers (Gsell, 1952), but differs from the pattern hitherto reported in Britain, where jaundice due to *L. icterohaemorrhagiae* and meningitis due to *L. canicola* are the commonly diagnosed forms of leptospirosis.

Subjects.—Nineteen British and 25 Gurkha soldiers had contracted leptospirosis between 1 and 14 years previously (mean eight years), when aged 18 to 28. Of these, four had developed anuria with a blood urea level of over 350 mg./100 ml. and two required haemodialysis, in eight the blood urea level had exceeded 150 mg./100 ml., and the remainder had normal or slightly impaired renal function with albumin, cells, and granular casts in the urine. The original clinical diagnosis had been confirmed by laboratory and serological findings (Trimble, 1957; Ross Russell, 1959). Most of the patients had been treated with large doses of penicillin by intramuscular injection; this drug shortens the duration of the illness and may produce a Herxheimer type of reaction (Mackay-Dick and Robinson, 1957). The patients were selected solely on grounds of availability and represent aproximately a 30% sample of currently serving soldiers who have had leptospirosis. As no soldier has been medically discharged from the Army because of this disease it is unlikely that our series is biased in favour of the fittest.

Methods.—Each patient was admitted to hospital for assessment. Biochemical methods were as described by Varley (1962). Urine specific gravity was measured at room temperature (15–23° C.) by standard hydrometers. In the urine concentration test dehydration was not prolonged beyond 16 hours.

Results

No patients had symptoms or were anaemic (Hb<13.5 g./100 ml.) and only one was hypertensive (B.P.>130/90 mm. Hg). His B.P. was 115/70 at the time of the attack, but three years later it was 170/120 and the E.C.G. showed hypertensive changes.

Examination of two fresh morning midstream specimens of urine for albumin, glucose, and deposit gave normal results. The blood urea level (mean of two estimations) was in the range 16–35 mg./100 ml. The creatinine clearance, corrected to a body surface area of 1.73 sq. m., was twice estimated over 24 hours in the British soldiers and exceeded 90 ml./min. in all except one. In this patient, who was not hypertensive, the values were 60 and 63 ml./min., but the results of other tests (including kidney length as visualized on a plain *x*-ray film) were normal. Single estimations of the creatinine clearance in eight Gurkha soldiers investigated in one hospital (group A) gave values of over 90 ml./min. Of the 17 assessed elsewhere (group B), seven had values of less than 90 ml./min., but the serum creatinine levels were similar to those of the patients with normal clearances.

All the British patients concentrated urine to a specific gravity of at least 1020 and diluted to a specific gravity of at least 1002, the narrowest range being 1022–1002. The results were similar in the Gurkha patients in group B, but of the eight in group A five did not concentrate to this degree.

A plain *x*-ray film of the renal area was taken in each case and it was possible to measure the length of both kidneys in 12; the overall range was 12–14.5 cm., and in no instance did the difference between the two sides exceed 1 cm. Intravenous pyelograms were performed in four men (including the patient with hypertension) who were reviewed between one and eight years after the attack of leptospirosis; all showed normal renal anatomy and secretion. In two of these patients ^{131}I Hippuran renograms were performed, with normal results.

There was no correlation between the severity of the initial renal lesion and the blood urea level, creatinine clearance, and maximum specific gravity of the urine, nor did the length of the interval betwen the acute attack and reassessment influence these results.

Dr. L. H. Turner, of the London School of Hygiene and Tropical Medicine, examined the sera of 12 British patients, using pools of formolized leptospiral antigens based on the currently accepted arrangement of serogroups and designed to detect all known pathogenic serotypes. Each showed agglutinin titres of 1:30 to 1:100 against at least two, and in some

§ Major, R.A.M.C.; British Military Hospital, Terendak, Malaysia.

instances six, serotypes. In only two were the maximum titres against the serotypes responsible for the original infection.

Discussion

Our results suggest that the long-term prognosis after the acute renal lesion of leptospirosis is good. Thus in the British patients all the results of renal function tests were normal except for a slightly reduced creatinine clearance in one man ; as the serum creatinine level and other results in him were normal the significance of this isolated finding is doubtful. Another man developed hypertension, but renal damage did not appear to be the cause. One group of Gurkha patients had normal creatinine clearances but all did not concentrate urine adequately, while in the others these findings were reversed ; since each abnormality was confined to one group it seems likely that these discrepancies reflect incomplete dehydration and incomplete urine collection respectively.

As intravenous pyelograms were performed in only four patients, and renal biopsy in none, we cannot be certain that permanent minor anatomical damage to the kidneys has not occurred ; but as the individual results were not influenced by the severity of the initial renal lesion or the time interval before reassessment it is unlikely that there is an active process present causing progressive destruction of renal tissue.

The finding of leptospiral agglutinins in the sera of the 12 patients examined is of interest, though in only two did the serological pattern parallel that of the original infection. Hart (1967), using the sensitized erythrocyte lysis test, has shown that a small proportion of soldiers serving in jungle areas in South-east Asia develop a rising titre of leptospiral antibodies without clinical evidence of infection, and our patients have served in this area on several occasions since their original illness. It is thus conceivable that they have acquired subclinical infections during this time and that this explains the serological findings. As, however, all our patients showed significant titres of agglutinins, and none of them had a clinical attack, which would be surprising if they were frequently exposed to infection, this explanation may be too facile. Further investigation of this point is required.

Summary

Renal function was studied in 44 soldiers who had contracted leptospirosis in South-east Asia up to 14 years previously. The findings suggest that renal function is now normal, and individual results do not reflect the severity of the initial renal damage or the time interval before reassessment.

The sera of 12 patients were examined for leptospiral agglutinins. All showed significant titres, but in only two were these against the serotype responsible for the original illness. These results may possibly reflect subclinical leptospiral infections contracted during later periods of service in the same area, but the present evidence is insufficient to allow firm conclusions to be drawn.

We wish to thank Dr. Gordon Smith, Director M.R.E., Porton, and Major-General R. J. G. Morrison, Consultant Physician to the Army, for suggesting and encouraging this investigation ; Dr. L. H. Turner for the serological results and advice ; Captain K. Hedges, R.A.M.C., for his help in arranging for the investigation of patients under his care ; and the Director-General, Army Medical Services, for permission to use case records.

Requests for reprints should be sent to Major B. Simpson.

Effect of Medical and Surgical Vagotomy on Intrinsic Factor Secretion

J. F. ADAMS,* V.R.D., M.D., F.R.C.P.ED., F.R.C.P.GLASG. ; A. G. COX,*† M.D., F.R.C.S.ED.
ELIZABETH H. KENNEDY,*‡ B.SC. ; J. THOMPSON,*§ M.B., M.R.C.P.GLASG.

Brit. med. J., 1967, 3, 473–476

The recent development of in-vitro techniques for the assay of gastric intrinsic factor has made possible the study of the effects of various pharmacological and surgical manœuvres on this facet of gastric secretory function. Using one such technique, we have studied the effects of pharmacological vagal blockade—" medical vagotomy "—in a group of patients with proved duodenal ulceration, and in some of these have also studied the effects of section of the vagus nerves.

Material and Methods

Twenty-six patients (23 men aged 22–60 and 3 women aged 42–48) with the clinical and radiological features of chronic duodenal ulceration were studied before operation, and further studies were made in 15 of them after operation. Vagotomy and pyloroplasty were performed on six men and one woman and vagotomy and gastrojejunostomy on six men and two women. The augmented histamine test was carried out in 26 cases before operation and in 15 after operation. Medical vagotomy was carried out in 25 cases before operation. The insulin test was done in 15 cases after operation. The choice of pyloroplasty or gastrojejunostomy was determined by a randomization procedure. The completeness of surgical vagotomy was confirmed in all cases by an insulin test.

The augmented histamine test (Kay, 1953) was performed after an overnight fast. Gastric aspiration was maintained by continuous suction. After collection of basal secretion in 15-minute periods for one hour, 100 mg. of mepyramine maleate was injected intramuscularly. Thirty minutes later histamine acid phosphate, 0.04 mg./kg. body weight, was injected subcutaneously and gastric aspiration was continued for a further hour, again in 15-minute collection periods.

* Southern General Hospital and University Department of Surgery, Western Infirmary, Glasgow.

† Now Senior Lecturer in Surgery, Royal Postgraduate Medical School, London.

‡ Now Scientific Officer, National Engineering Laboratory, East Kilbride, Lanarkshire.

§ Now Lecturer in Dermatology, University and Western Infirmary, Glasgow.

The medical vagotomy test (Gillespie and Kay, 1961) was carried out on another day. This differed from the standard augmented histamine test in that a combined intramuscular injection of 50 mg. of hexamethonium bromide, and 0.325 mg. of atropine, was given at the beginning of the test.

The insulin test was performed with a standard dose of 20 units of soluble insulin given intravenously after collection of three 15-minute specimens of spontaneous secretions. After the injection gastric aspiration was continued for two hours. Vagotomy was regarded as complete only if the acid concentration failed to rise 20 or more mEq/l. over the maximal basal level.

The volume and *p*H of all specimens of gastric juice were measured. The amount of acid was determined by titration to *p*H 7 with N/10 NaOH, phenol red being used as the indicator. Intrinsic factor assays were performed by the method of Gottlieb *et al.* (1965). Several sera containing antibody to intrinsic factor were used, all being of high potency. When the total binding exceeded 75% of the amount of radioactive cyanocobalamin added (usually 7.5 mμg.) the procedure was repeated with half the normal amount of neutralized gastric juice: if the total binding still exceeded 75% of the amount of radioactive cyanocobalamin added then the procedure was repeated with half the normal amount of neutralized gastric juice and double the normal amount of radioactive cyanocobalamin. For convenience we adopted the convention of expressing intrinsic factor activity in terms of units, one unit being taken as the specific intrinsic factor binding of 1 mμg. of radioactive cyanocobalamin.

The results were analysed by standard statistical methods.

Results

All results are given as hourly values, representing spontaneous secretion ("basal hour"), the augmented histamine response ("augmented histamine hour"), and the response to histamine after medical vagotomy ("medical vagotomy hour").

Effect of Histamine Stimulation

The mean values for volume, acid, intrinsic factor output, and intrinsic factor concentration were all significantly higher ($P<0.01$) in the augmented histamine hour than in the basal hour (Table I).

Correlation between Acid and Intrinsic Factor Output

An insignificant correlation was found between the mean values for acid and intrinsic factor in the basal hours, both before and after operation. However, a significant ($P<0.01$) correlation was found between these two measurements in the augmented histamine hours both before and after operation, and also in the medical vagotomy hour (Table II).

TABLE II.—*Correlation and Regression Equations*

Series	Period	Regression of y (I.F.) on x (Acid)	No. of Patients	r
All patients	Histamine hour ..	$y = 3{\cdot}085x + 60{\cdot}045$	26	0·551
	Medical vagotomy hour . ..	$y = 4{\cdot}773x + 34{\cdot}629$	25	0·585
Surgical group	Preoperative histamine hour ..	$y = 4{\cdot}926x + 25{\cdot}947$	15	0·693
	Medical vagotomy hour	$y = 7{\cdot}419x + 15{\cdot}0965$	14	0·751
	Postoperative histamine hour ..	$y = 7{\cdot}759x + 18{\cdot}652$	15	0·762

Effect of Medical and Surgical Vagotomy

The results are most conveniently considered in two groups. The first relates to the effect of medical vagotomy on the augmented histamine response. The second relates to the effect of surgical vagotomy on basal secretion and the augmented histamine response.

Medical Vagotomy.—The mean values for volume and acid were significantly less ($P<0.01$) in the medical vagotomy hour than in the augmented histamine hour. Differences in the mean values for intrinsic factor output and concentration did not

achieve significance, though the mean intrinsic factor output was lower and the concentration higher in the medical vagotomy hour. The detailed results (Table III) show the very marked individual variations in response.

Surgical Vagotomy.—The effect of surgery on basal secretion was a significant reduction in mean values for volume, acid, and intrinsic factor ($P<0.01$) and for intrinsic factor concentration ($P<0.05$). The effect of surgery on histamine-stimulated secretion was a significant reduction in mean values for volume, acid ($P<0.01$), and intrinsic factor output ($P<0.05$), but there was no significant change in mean values for intrinsic factor concentration. Patients having gastrojejunostomy did not differ from those in whom pyloroplasty was employed as the drainage procedure. Detailed results (Table IV) again showed very marked individual variation in response. The pattern of response to histamine after operation was similar to that found during medical vagotomy (see Chart).

Secretory patterns in cases studied before and after surgery. The figures 5–8 signify the four 15-minute periods after the injection of histamine, 1–4 being the four 15-minute periods before the injection.

Comparison of Effects of Medical and Surgical Vagotomy.—Comparison of the mean hourly values after medical vagotomy and after histamine stimulation in the postoperative period showed that the mean values for volume and intrinsic factor did not differ significantly ($P>0.05$) but that the mean values for acid and intrinsic factor concentration were significantly less ($P<0.01$ and <0.05 respectively) after operation than after medical vagotomy.

Discussion

The object of this study was to determine and compare the effects of medical and surgical vagotomy on gastric secretory function with particular emphasis on intrinsic factor secretion, and discussion of the results is limited to these points.

During the course of the study Bitsch *et al.* (1966) published their findings on the effects of surgical vagotomy on gastric secretory function, and comparison of the two sets of results is desirable. The mean values for volume, acid, intrinsic factor, and intrinsic factor concentration found by us are less than those of Bitsch *et al.*, but the data given in their paper do not permit calculation of the significance of these differences. The results can be compared, however, by taking the difference between the values obtained in the histamine hour before and after operation and expressing the difference as a percentage of the preoperative value. Bitsch *et al.* observed a volume reduction of 46.7%, an acid reduction of 62.5%, and a reduction in intrinsic factor output of 43.8% (not 34% as printed in their paper). The corresponding values in the present study are 40.8% for volume, 66.8% for acid, and 44.9% for intrinsic factor. These results are clearly in close agreement and confirm that surgical vagotomy and a drainage procedure effect a significant reduction in the output of gastric juice, acid, and intrinsic factor in response to histamine.

The type of drainage procedure employed does not appear to be important. In our series both groups responded in a similar manner and no significant differences were found between them in regard to volume, acid, or intrinsic factor output after operation. This suggests, but does not prove, that vagotomy is the effective agent.

The effect of medical vagotomy differs sharply from that of surgical vagotomy. The effect of medical vagotomy was a significant reduction in volume and acid output after histamine stimulation, as was expected (Gillespie and Kay, 1961), but an insignificant change in intrinsic factor output. This finding is of interest in relation to the mechanisms which control intrinsic factor secretion. Hoedemaeker *et al.* (1964) have produced evidence from immunological and autoradiographic studies that the site of secretion is the parietal cell, and this view is supported by the close correlation between amounts of acid and intrinsic factor secreted (Ardeman, 1965; Irvine, 1965; Rødbro, *et al.*, 1965). The pattern of acid and that of intrinsic factor secretion differ, however, the difference being most obvious on continued histamine stimulation when the output of acid remains high and that of intrinsic factor falls off rapidly after an initial rise (Irvine, 1966; Lawrie and Anderson, 1967). This indicates either that the two secretions come from different cells or that they come from the same cell, in which case the secretion of acid is by a process of true stimulation and that of intrinsic factor is one of release or "washout." The importance of vagal control is clearly shown by the effect of surgical vagotomy as found by Bitsch *et al.* (1966) and confirmed here.

That medical vagotomy did not have a quantitatively significant effect on the histamine-stimulated output of intrinsic factor was therefore unexpected but is not necessarily evidence against the concept of vagal control of intrinsic factor secretion. The pattern of intrinsic factor secretion is affected by medical vagotomy in the same way as by surgical vagotomy, suggesting that both procedures exert an effect on the controlling mechanisms even if the effect is quantitatively insignificant with one but not with the other. There are two possible explanations. First the vagal component of acid secretion may be more dominant than the vagal control of intrinsic factor secretion, and since medical vagotomy is less complete than surgical vagotomy the quantitative effect will be correspondingly less. Other influences on intrinsic factor secretion, such as intragastric reflexes, may be more important than the vagal component. Secondly, the medical vagotomy differs from surgical vagotomy in that it fails to block histamine-stimulated washout effect while having a blocking effect on the pattern of active secretion stimulated by histamine.

Summary

The effect of medical and surgical vagotomy on intrinsic factor secretion was studied in patients with duodenal ulceration.

Surgical vagotomy brought a significant reduction in both basal and histamine-stimulated output, but medical vagotomy did not significantly affect histamine-stimulated output. The pattern of intrinsic factor secretion in response to histamine was affected in the same manner by medical and surgical vagotomy.

The results suggest either that the vagal component in the control of intrinsic factor secretion is less dominant than the vagal component in acid secretion or that medical vagotomy differs from surgical vagotomy, the former failing to block a washout type of pattern and the latter doing so.

We are grateful to Professor A. W. Kay for advice and encouragement, to Professor T. Ferguson Rodger for facilities in his department, and to Merck Sharp & Dohme Ltd. for supplies of radioactive cyanocobalamin. We acknowledge with thanks a grant from the Secretary of State for Scotland on the advice of the Advisory Committee on Medical Research.

Medical Memoranda

Hydatidiform Mole and Coexistent Foetus, both with Triploid Chromosome Constitution

Brit. med. J., 1967, **3**, 476–478

Triploid chromosome complement in man has been described in abortions and also in three living subjects, all of whom were mosaics (Böök and Santesson, 1960 ; Penrose and Delhanty, 1961 ; Delhanty *et al.*, 1961 ; Carr, 1963, 1965 ; Ellis *et al.*, 1963 ; Ferrier *et al.*, 1964 ; Thiede and Salm, 1964 ; Aspillaga *et al.*, 1964 ; Szulman, 1965).

Atkin and Klinger (1962) and Szulman (1965) have reported a case of mole with an associated foetus in which triploidy was found in the molar tissue. Makino *et al.* (1964) found triploid chromosome complements in three cases of early abortion, where the chorionic villi were swollen and oedematous, forming small vesicles as in hydatidiform mole. Carr (1965) in his later series described a similar case. In none of these molar or molar-like gestations were the clinical features reported.

This paper describes the finding of triploid chromosome complement in a hydatidiform mole and its associated abnormal foetus, the mother showing antepartum and postpartum clinical features of molar pregnancy.

CASE REPORT

A 22-year-old woman developed severe pre-eclampsia at 17 weeks of gestation in her first pregnancy. She had palpitations, severe dyspnoea, and pain in the right iliac fossa when referred to the Royal Women's Hospital seven weeks later. The haemoglobin had fallen from 13 to 7.1 g./100 ml., though vaginal bleeding had not occurred. The blood pressure was 170/110 and the urine contained 20 g. of protein per litre. The right lower abdomen was tender, but no mass was felt apart from the uterus, which reached to the level of the umbilicus. *X*-ray examination showed a foetal skeleton commensurate with 18 rather than 24 weeks of development ; the plasma uric acid was 4.7 mg./100 ml. ; urinary oestriol 1.5 mg./24 hours, and urinary chorionic gonadotrophin 300–400 i.u./ml.

After treatment with sedation and hypotensive drugs artificial rupture of the membranes was performed and 300 ml. of amniotic

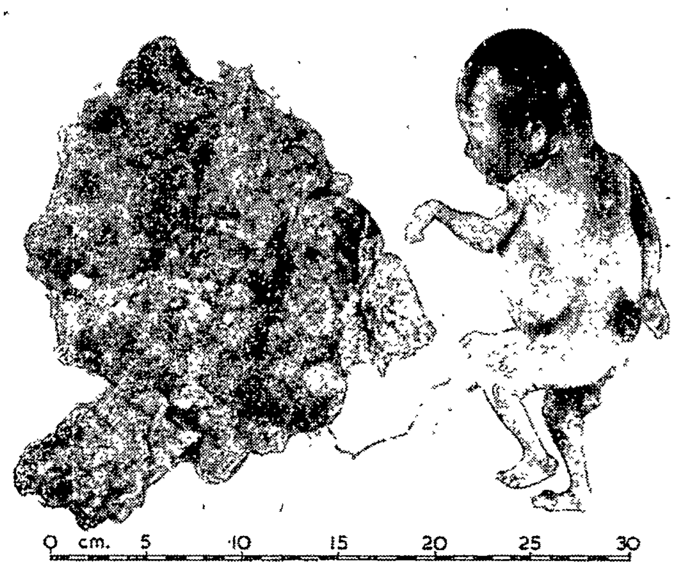

FIG. 1.—Malformed foetus together with placenta showing diffuse macroscopic molar degeneration.

fluid was obtained. As vaginal bleeding then occurred, a blood transfusion was begun. An oxytocic infusion was given, and after a five-hour labour the patient aborted the conceptus shown in Fig. 1, and within 10 minutes became cyanosed and acutely dyspnoeic. Crepitations were heard throughout the lungs, and chest *x*-ray examination (Fig. 2) showed consolidation extending from the left hilum and congestive changes at both bases. The patient responded to treatment with oxygen and aminophylline, and within six days the lung fields were clinically and radiographically clear, the urine was free of protein, and the blood pressure had subsided to 140/85. The patient had remained well when seen six months later.

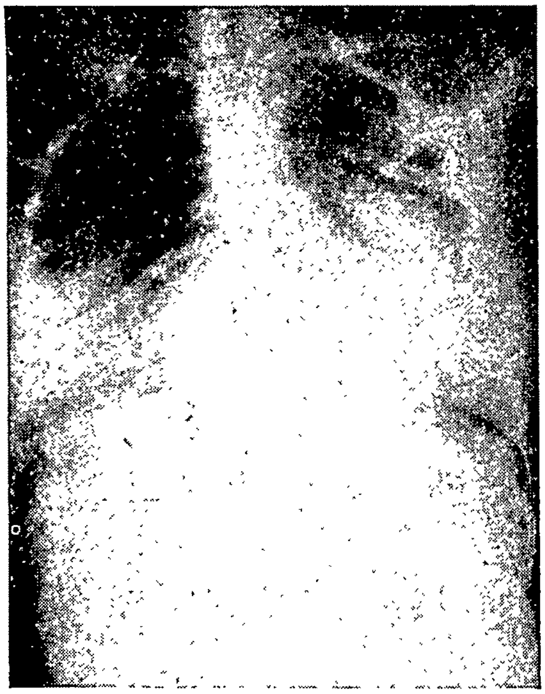

FIG. 2.—Chest *x*-ray film two hours after delivery, showing consolidation in both lung fields.

The molar condition of the placenta was presumably the cause of the patient's pre-eclampsia. The abdominal pain and fall in haemoglobin are explained by retromolar haemorrhage. The acute heart failure after delivery may have been the result of molar emboli caused by the oxytocic infusion. Hendrickse *et al.* (1965) reported 25 cases of acute dyspnoea complicating trophoblastic tumours, and three patients in their series had benign hydatidiform mole. We have seen only one other patient with acute heart failure and hydatidiform mole, and she also had a mole with associated foetus.

The abortus is of particular interest because the molar condition of the single placenta was diffuse and the female foetus abnormal, both on macroscopic inspection and on chromosomal analysis.

PATHOLOGY REPORT

The placenta was 15 cm. in diameter and the cord 30 cm. in length. Throughout the placenta numerous vesicles were visible, the majority being 0.5–1 cm. in diameter and some as large as 4 cm. When incised the vesicles released clear fluid. Apart from the obvious vesicles, closer examination with the dissecting microscope showed a mixture of swollen and relatively normal villi. The cord and membranes were normal.

The foetus was female, weighing 350 g., crown–heel length 27 cm., crown–rump length 17 cm. It showed bruising and oedema of the scalp tissues, effusions in the serous cavities, and a lumbar meningomyelocele 2 cm. in diameter. On dissection the brain was found to be grossly abnormal, with complete absence of corpus callosum and septum pellucidum, and hyperplasia of the cerebellum. Underlying the meningomyelocele, the vertebral column showed posterior spina bifida involving the lower four lumbar vertebrae. The left kidney was enlarged and polycystic with no normal renal tissue identifiable, and measured 3 by 2 by 4 cm. The right kidney contained several small cysts in the medullary zone.

Microscopical examination of the placenta (Fig. 3) showed swollen, oedematous, poorly vascularized villi. Some of the larger villi were cystic, with a thin wall of stromal tissue and a lining of flattened cells next to the cavity. Other villi were swollen and oedematous but contained dilated vessels. Some of the vessels in supporting villi appeared thickened. The remaining smaller villi were like those seen in full-term placentae. Trophoblastic proliferation was present over some of the villi, but was not pronounced.

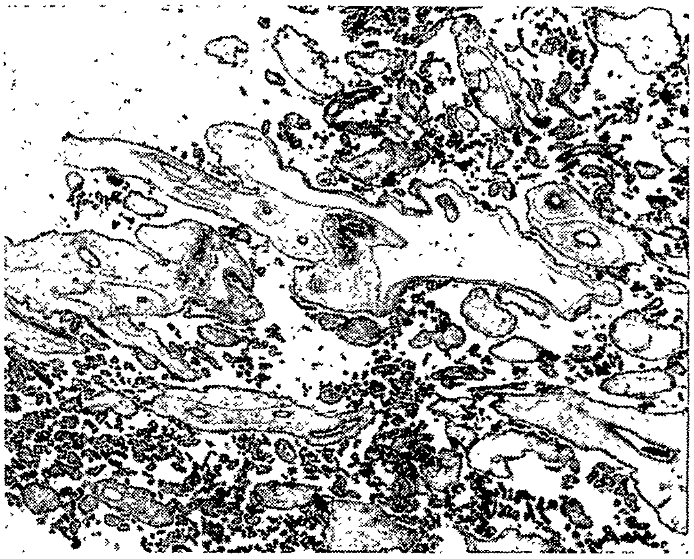

FIG. 3.—Section of placenta showing a mixture of hydropic and relatively normal villi. (H. and E. ×9.)

The left polycystic kidney showed scattered collections of glomeruli and tubules, and cysts which seemed to be of tubular origin. The few cysts in the right kidney were of similar origin.

CYTOGENETIC STUDIES

Cultures of foetal peripheral blood, thymus, and cord were set up and also vesicular tissue from the mole.

Suitable metaphase plates for counting and detailed analysis were obtained from all tissues, though the yield from the molar tissue was low. A modal count of 69 chromosomes was found (Table I) and karyotyping showed a triploid constitution (3A 3X) (Fig. 4). In many of the karyotypes and particularly in the larger groups two of each trio appeared morphologically similar, suggesting a common origin, as was observed in triploidy by Ferrier *et al.* (1964).

TABLE I.—*Chromosome Number Distribution in Foetal and Molar Tissues*

Tissue	Chromosome Number					No. of Cells Counted	Sex Chromosomes

Kidney	35	58	9	200
Lung	41	51	8	200
Liver	36	54	10	100
Brain	27	62	11	200
Adrenal	30	59	11	100
Skin	22	62	16	300
Cord cultures	54	30	6	300
Mole „	70	28	2	300

The reported incidence of sex chromatin in triploid tissues has been variable; therefore counts were made on various foetal tissues, the mole, and cultured cells (Table II). Since some of the foetal tissues were not as well preserved as others, only characteristic chromatin masses on the nuclear membrane were scored, thus lowering the tissue incidence of single and double chromatin masses. The occurrence of sex chromatin was nevertheless shown to be remarkably consistent in molar and foetal tissues, with a lower incidence in the cultured tissues from cord and mole.

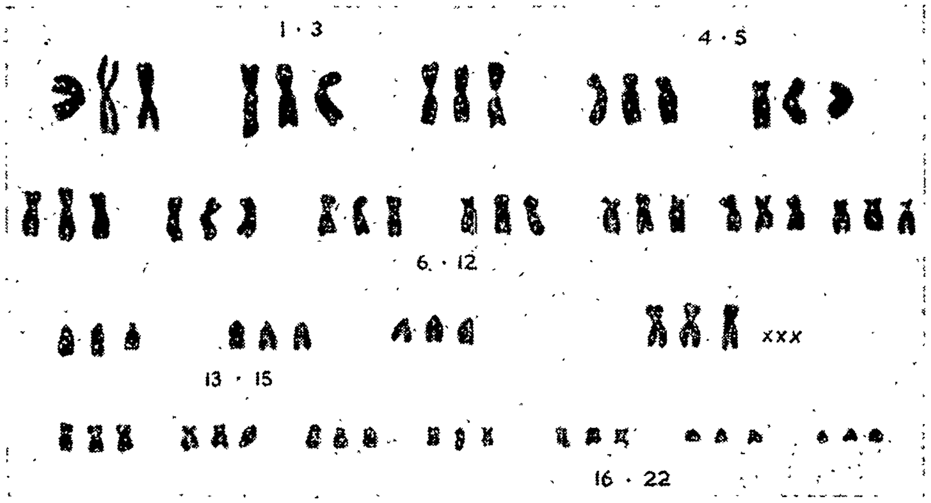

FIG. 4.—Triploid karyotype with XXX sex chromosome constitution.

DISCUSSION

Of 82 cases of mole with coexistent foetus abstracted from the literature 52 were associated with a single placenta and 30 were cases of dizygotic twins in which the molar tissue was separate from the normal placenta associated with the foetus (Beischer, 1966). There were eight abnormal foetuses among those associated with a single placenta, and in two spina bifida with meningomyelocele was described along with other malformations. The case reported above falls into this group of abnormal pregnancies and shows an associated chromosomal abnormality.

Fig. 5 shows a female foetus with meningomyelocele and its associated single molar placenta. This specimen was obtained by hysterotomy performed because of severe pre-eclampsia at 16 weeks of gestation and was reported in a previous paper (Beischer, 1961, Case 8). Because of the similarities between this case and the one reported here, we have carried out sex chromatin studies on both foetal and molar tissues; nuclei containing two sex chromatin masses were found in the stromal cells of the mole with single masses in the trophoblast and several types of foetal tissues. It is therefore probable that a triploid cell line was present in the mole with an XXX sex chromosome constitution. Atkin and Klinger (1962) mention developmental abnormalities in their case of foetus with single molar placenta, where they found a triploid chromosome constitution in the mole and double sex chromatin masses in some of the nuclei of the foetal tissues.

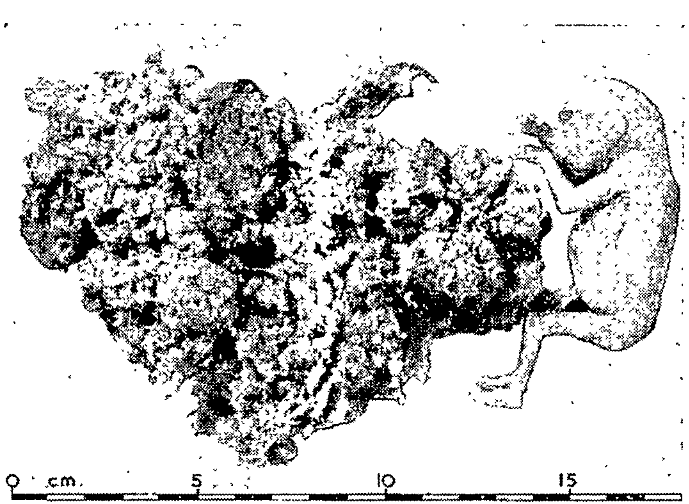

FIG. 5.—Abnormal female foetus with a single placenta showing complete macroscopic molar degeneration.

There is, therefore, accumulating evidence that certain molar pregnancies are associated with chromosomal abnormalities, and at present triploidy is most frequently reported. Where a single molar placenta is associated with a foetus the latter is often abnormal, and developmental defects of the central nervous system are not uncommon.

We wish to thank Miss S. Searle for technical assistance and Miss M. L. Johnson for the photographs.

Current Practice

GROWING POINTS

Autoimmune Disease—II*

G. L. ASHERSON,† D.M., M.R.C.P.

The first part of this article described the way in which autoimmune responses—namely, autoantibodies, delayed hypersensitivity, and sometimes tissue damage—could be produced in animals. These autoimmune responses occur when (*a*) the animal is exposed to antigens similar to but not identical with self; (*b*) the animal is exposed to its own body constituents, together with an adjuvant such as Freund's complete adjuvant; and (*c*) spontaneously in New Zealand black mice. The tissue damage seen is regarded as autoimmune in nature because

(1) It is provoked by the injection of the appropriate organ, preferably in Freund's complete adjuvant, which increases and modifies immune responses. Well-characterized antigens such as thyroglobulin are able to cause autoimmune disease.

(2) It can be prevented by treatment with cortisone and folic-acid antagonists under conditions which limit immune responses, and by antigen under conditions which limit delayed hypersensitivity.

(3) The histology of the affected organ, showing infiltration with lymphocytes and histiocytes, is characteristic of delayed hypersensitivity.

(4) In the case of allergic encephalomyelitis the lesions can be transferred to normal recipients by spleen cells.

(5) Circulating autoantibodies can be demonstrated.

It is possible to cause autoantibody formation in animals, however, without producing tissue damage. For instance, rats injected with carbon tetrachloride produce autoantibodies against their own livers which are not thought to damage the liver.

It is easy to recognize disease produced by the injection of antigen as autoimmune. In man, allergic encephalomyelitis sometimes follows the injection of rabbit spinal cord used in the treatment of suspected rabies. The post-cardiotomy and post-myocardial-infarction syndromes sometimes follow damage to the heart, and the autoimmune response is probably responsible for the clinical picture. Ligation of the vas deferens by making available or altering testicular antigen causes the formation of autoantibody to sperm. These are probably responsible for infertility in some patients.

In most cases, however, the agent causing an autoimmune response is unknown, and this makes it difficult to determine whether the autoimmune response causes tissue damage or whether tissue damage gives rise to an autoimmune response. There are three possibilities:

(A) The initiating agent causes an immune response which is responsible for the main features of the disease. An example is human encephalomyelitis produced by rabbit spinal cord. If the tissue damage caused by the autoimmune response leads to further damaging autoimmune responses the disease will be self-perpetuating.

(B) The initiating agent causes tissue damage leading to an autoimmune response which is responsible for the main features of the disease. The post-cardiotomy syndrome is a possible example. Here again the autoimmune response may be self-perpetuating.

(C) The initiating agent causes the tissue damage and is responsible directly for the clinical and pathological changes of the disease. The autoimmune response is a result of the tissue damage, or is a direct effect of the initiating agent but is unimportant in pathogenesis. The formation of autoantibodies to pancreas seen in obstruction of the pancreatic duct is a possible example.

Because it is often uncertain whether an autoimmune process is the result or cause of disease, the term putative autoimmune disease is used in this article. There are certain common features of putative autoimmune diseases. These are:

(i) Raised serum gammaglobulins, which offer indirect evidence of immunological activity because antibodies are gammaglobulins.

(ii) Direct evidence of an autoimmune response, as shown by autoantibody and delayed hypersensitivity.

(iii) Tissue lesions characterized by infiltration with lymphocytes, histiocytes, and plasma cells.

(iv) Genetic incidence of the disease, and clinical and serological association with other autoimmune diseases, in either the patient or his family.

(v) Association with enlargement of the thymus or thymic tumour or both.

(vi) Ameliorating effect of corticosteroids and cytotoxic drugs.

(vii) Production of similar disease of an autoimmune aetiology in animals.

The occurrence of these features in a disease provides evidence that it resembles other putative autoimmune diseases.

Diseases in which Autoimmune Reactions may be Provoked by Micro-organisms

Rheumatic Fever.—This disease is always associated with group A beta-haemolytic streptococcal infection. These organisms have an antigen similar to human heart. Autoantibodies which react with streptococcal extracts, and can be absorbed by the human heart, may be found by gel-precipitation techniques in acute rheumatic fever. They also occur in acute glomerulonephritis and less frequently in uncomplicated streptococcal pharyngitis. The autoantibodies probably arise because of exposure to streptococcal antigen resembling human heart. The cause of tissue damage is less clear. Patients with rheumatic heart disease who undergo cardiac surgery have an increased incidence of post-cardiotomy syndrome, compared with patients with congenital heart disease. This syndrome is characterized by precordial pain, fever, and pericardial effusion. There are autoantibodies against heart, and the response to steroids is good. The raised incidence in subjects with past rheumatic fever may be related to the fact that they have already produced an autoimmune response to heart tissue.

Acute Glomerulonephritis.—This is associated with certain strains of group A beta-haemolytic streptococci. The type-12 nephritogenic strain has antigens similar to those of renal glomeruli. Acute glomerulonephritis is one of the few diseases (systemic lupus erythematosus is another) in which the level of serum complement is low. A low serum-complement level provides some evidence of complement-fixing antigen-antibody reactions *in vivo*. Serum complement is often raised when there is tissue damage, and not all immune reactions fix complement. Hence the finding of normal serum complement is not evidence against the presence of immunological disease.

---

* The first part of this article appeared in last week's issue (p. 417).

† Reader in Immunology, Department of Bacteriology, the London Hospital Medical College, London E.1.

Renal Disease.—Renal damage is a common cause of death in systemic lupus erythematosus, and it is often suggested that various forms of glomerulonephritis are immunological in nature. There are several different methods of producing immunological renal disease:

(*a*) Masugi nephritis, caused by the injection of antikidney serum. For a long time this was the chief evidence that renal disease might be immunological.

(*b*) Immune response to foreign antigens adhering to the glomeruli. Certain bacterial antigens adhere to the glomeruli, and immune responses against them may cause renal damage.

(*c*) Injection of kidney tissue in Freund's complete adjuvant. This may be an example of an autoimmune response against the kidney.

(*d*) Circulating antigen-antibody complexes. When antibody is mixed with an excess of antigen soluble antigen-antibody complexes are formed. These complexes are often able to bind (fix) complement and to cause renal damage. Their presence in the circulation is usually associated with a low serum-complement level, and they may be responsible for the renal damage in systemic lupus erythematosus.

The demonstration of gammaglobulin bound to the tissues by immunofluorescence is often taken as evidence of local combination of antibody and antigen. The presumption is strengthened by the demonstration of complement in the lesion by immunofluorescence. Nevertheless, bound gammaglobulin is seen in the glomeruli in certain experimental diseases of non-immunological nature, and this evidence requires careful assessment in renal disease.

Ulcerative Colitis.—In about 10% of these patients autoantibodies to colon can be demonstrated by immunofluorescence. Autoantibodies can also be demonstrated by haemagglutination, using red cells coated with polysaccharide derived from colonic tissue. These autoantibodies react with an antigen which occurs in sterile human and rat colon, and in certain strains of *Esch. coli.* The suggestion is that these autoantibodies arise because the human body is stimulated by bacterial antigens similar to but not identical with its own tissue components. But it is not certain that autoantibody production is an important part of the disease, and it is possible that immune reactions to bacterial residues in the tissues has a more central role. In some cases food allergy, particularly to milk, is important; and in controlled trials withdrawal of milk has been shown to diminish the frequency of relapse.

Coeliac Disease.—Antibodies to gluten show a high frequency and titre in patients with coeliac disease. There is no evidence that this is an autoimmune disease, but it may be an immune reaction to foreign antigens. Autoantibodies to gut occur in pernicious anaemia and ulcerative colitis, and in both of these the incidence of carcinoma of the affected organ is raised. In coeliac disease the incidence of lymphosarcoma of the small intestine is raised (but this is still low).

Glandular Fever.—Autoantibodies against formed elements of the blood are sometimes found, and they may be responsible for haemolytic anaemia and thrombocytopenia. The virus has not been isolated, and we do not know whether it shares antigens with human tissue.

Primary Atypical Pneumonia.—This is due to *Mycoplasma pneumoniae.* Cold agglutinins (which are autoantibodies directed against the I antigen of human erythrocytes) are often found, and they may present clinically as Raynaud's phenomenon or haemolytic anaemia and jaundice on exposure to cold. A raised titre of antibodies to *M. pneumoniae* is sometimes found in the Stevens–Johnson syndrome.

Hashimoto's Thyroiditis Group of Diseases

This group of diseases includes Hashimoto's thyroiditis, pernicious anaemia, and non-tuberculous Addison's disease of the adrenal. Certain forms of hypoparathyroidism and diabetes may ultimately be shown to belong to this group. The diseases have several common features:

(I) Autoantibodies occur which react with the affected organ, and can be demonstrated by complement fixation and immunofluorescence. Autoantibody against cell secretions—thyroglobulin and intrinsic factor—occur in Hashimoto's thyroiditis and pernicious anaemia.

(II) Patients with one disease commonly have autoantibodies characteristic of the other diseases of the group. These autoantibodies are called organ-specific, because they react with antigen from one organ only. In contrast, the autoantibodies in systemic lupus erythematosus react with widely distributed nuclear and cytoplasmic antigens. These non-organ-specific antibodies are rare in the Hashimoto's thyroiditis group of diseases.

(III) Patients sometimes have more than one disease in the group.

(IV) The patients give a family history of their own disease and of other diseases in the group.

These diseases are clinically important, because they may present insidiously and simulate psychological disorders.

Nearly all patients with Hashimoto's thyroiditis have autoantibodies against thyroid by at least one test, and the diagnosis is usually wrong if the tanned-cell-haemagglutination test for thyroglobulin, the complement-fixation reaction for antibody against cytoplasmic antigen, the immunofluorescent test for antibody against thyroglobulin, the second colloid antigen (CA2), and the cytoplasmic antigen are all negative. Low titres of antibody against thyroglobulin by the tanned-cell test are not uncommon, being shown in about 15% of women over the age of 50. Like many other autoantibodies which occur in a few apparently normal people, the incidence is much higher in women than in men. The complement-fixation reaction is rarely positive in the absence of disease. The immunofluorescent and complement-fixation tests for cytoplasmic antigen run in parallel. The immunofluorescent test is a little more sensitive (90% of patients with Hashimoto's thyroiditis give positive results), but there is a higher incidence of borderline positive results (0–15%) in apparently healthy subjects.

In the differential diagnosis of carcinoma of the thyroid and Hashimoto's thyroiditis the absence of autoantibodies is strong evidence against Hashimoto's thyroiditis. The converse is not true, and the presence of autoantibodies does not exclude carcinoma.

Tissue damage in these diseases is probably due to autoimmune processes. This is suggested by the histology of the affected organ, which is infiltrated with lymphocytes and histocytes, and the finding of autoantibodies. Cytotoxic antibodies to thyroid cells in tissue culture are almost invariably present in active Hashimoto's thyroiditis. The process which initiates autoantibody formation is unknown. The classical view was that the thyroid antigens were secluded and therefore unable to induce tolerance, but recently thyroglobulin has been demonstrated in the circulation. Perhaps its levels are too low or too variable for the maintenance of tolerance.

Graves's Disease.—Patients with Graves's disease have a thyroid-stimulating factor which behaves differently from thyrotrophic hormone, and is known as the long-acting thyroid stimulator or L.A.T.S. Recently it has been shown that L.A.T.S. is a gammaglobulin, which presumably acts by combining with the thyroid gland and stimulating the action of thyrotrophic hormone. The implication is that the hypersecretion in Graves's disease is due to an autoantibody. The thymus is usually enlarged in Graves's disease, and contains germinal centres, which are morphological evidence of antibody production. They are not found in the normal thymus. Similar changes are seen in myasthenia gravis and systemic lupus erythematosus, and in a few cases of Hashimoto's thyroiditis that have been examined. The incidence of autoantibodies to thyroid, as detected by conventional tests, is raised in Graves's disease. There is, however, a particularly high incidence of autoantibodies to thyroglobulin in exophthalmic goitre.

Pernicious Anaemia.—Autoantibodies against intrinsic factor are a distinctive feature of this disease, and they do not occur in patients with uncomplicated gastritis. They are detected by their effect on the electrophoretic mobility of radioactive-B_{12} intrinsic-factor complexes. Autoantibodies against the secretory cells of the stomach can be detected by complement-fixation and immunofluorescence in 50 to 90% of patients with pernicious anaemia. As in ulcerative colitis, the incidence of carcinoma of the affected organ is raised. The incidence of antibodies to stomach is increased in chronic gastritis (diagnosed by biopsy) and idiopathic iron-deficiency anaemia. Antibodies against stomach are not reported in infantile pernicious anaemia. These patients have normal acid secretion, and infantile pernicious anaemia is a distinct disease from the adult form.

Myasthenia Gravis and the Role of the Thymus

Autoantibodies against muscle have been demonstrated in myasthenia gravis. The techniques used for their detection include complement fixation, immunofluorescence, and tanned-cell haemagglutination. Autoantibodies are also produced against an antigen in the thymus, and occasionally against nuclei. Myasthenia gravis is sometimes associated with other putative autoimmune diseases, such as Graves's disease. Lymphorrhages (accumulations of lymphocytes) similar to those seen in thyrotoxicosis, Hashimoto's thyroiditis, and Addison's disease are found in the muscles. In this disease the relationship between the autoantibodies and the characteristic neuromuscular block is unknown.

The thymus is often enlarged, and contains germinal centres which provide morphological evidence of antibody production. In some cases there is a thymic tumour, and these patients characteristically have high titres of autoantibodies and respond poorly to thymectomy. Thymic tumours also associated with aplastic anaemia, dermatomyositis, polymyositis, granulomatous myocarditis, hyperglobulinaemic purpura, and hypogammaglobulinaemia. The question arises whether autoimmunity is important in any of these diseases.

The role of the thymus in disease is still obscure. In early post-natal life cells leave the thymus to populate the lymphoid system, and the thymus produces a hormone which favours the development of immunologically competent cells. The thymus is required in adult life for the rapid restoration of immunological function after damage to the lymphoid system by *x*-rays and other agents. The presence of germinal centres in the thymus in myasthenia gravis presumably reflects antibody production which may be directed against autoantigens.

Diabetes Mellitus

The possibility of autoimmune mechanisms in diabetes mellitus is under discussion. The most suggestive evidence is the association of Hashimoto's thyroiditis, Addison's disease, and sometimes hypoparathyroidism with diabetes (Schmidt's syndrome). Antibodies against insulin are commonly found in treated diabetics. They may be directed against human insulin, and arise as a result of stimulation with foreign insulin. They are sometimes responsible for insulin resistance.

Systemic Lupus Erythematosus and Related Diseases

Systemic lupus erythematosus is characterized clinically by multisystem involvement. The increase in gammaglobulin suggests increased antibody production. The wide range of autoantibodies characteristically react with widely distributed antigen, and these are described as non-organ-specific; the incidence of organ-specific autoantibodies of the type seen in the Hashimoto thyroiditis group of diseases is little altered.

The antibodies against nuclei (antinuclear factor) are usually detected by immunofluorescence. This test is nearly always positive in systemic lupus erythematosus, and diagnosis of the disease is nearly always wrong when the antinuclear-factor test is negative. The antinuclear-factor test, unlike the L.E.-cell test, is usually positive even when the disease is clinically inactive. The L.E.-cell test also detects antibodies against nuclei. It is positive much less frequently than is the antinuclear factor test, but there are very occasional patients with positive L.E. and negative antinuclear-factor tests.

Antibodies against cytoplasm are also found, and are detected by complement fixation—the autoimmune complement-fixation reaction. There is sometimes a biologically false-positive test for syphilis. Rheumatoid factor (which behaves like an antibody to altered gammaglobulin) occurs in about a third of patients. Autoantibodies against formed blood elements and coagulation factors may cause haemolytic anaemia, thrombocytopenia and bleeding disorders, and some cases of apparent idiopathic thrombocytopenia and thrombotic thrombocytopenic purpura develop features of systemic lupus erythematosus.

Patients with systemic lupus erythematosus have an unusual tendency to give drug and blood-transfusion reactions, and relapses may be provoked by drug reactions. In children the anticonvulsant drugs may precipitate an illness resembling systemic lupus erythematosus; the prognosis of this drug-induced disease is apparently better than that of the "idiopathic" disease. There is evidence that when patients with systemic lupus erythematosus are injected with antigens which do not cause autoantibody formation in normal subjects they produce a range of autoantibodies.

The histology of the thymus in systemic lupus erythematosus is of considerable interest. Lymphoid infiltrates and germinal centres are found, but few observations are available, because corticosteroids and terminal illness cause involution of the thymus.

The incidence of hypergammaglobulinaemia, antinuclear factor, and diseases of the systemic lupus erythematosus group is slightly raised in the relatives of patients with systemic lupus erythematosus, and in a few families the incidence of related disease is very high. The familial association with hypogammaglobulinaemia is an intriguing finding.

The aetiology of systemic lupus erythematosus is unknown, although New Zealand black mice provide a good natural model of the disease. Because of the many different autoantibodies found, this disease can be described as a disorder or breakdown of immune tolerance, but it is not clear whether this is due to exposure to altered antigens or to a defect in the antibody-producing system.

Rheumatoid Arthritis.—Rheumatoid factor, which behaves like an antibody to altered gammaglobulin (and some of the allotypes of gammaglobulin), is found in most patients with chronic rheumatoid arthritis showing joint erosions on radiological examination and nodules. It is often absent in the first year of the disease, and it is found in about 5% of normal subjects. Rheumatoid factor can be produced in animals by immunizing with antigen-antibody complexes; by infection, which probably acts by producing antibody–antigen complexes *in vivo*; and by immunization with altered gammaglobulin. Rheumatoid factor is often found in subacute bacterial endocarditis, where it has been suggested as a diagnostic aid, and in a range of diseases—including infectious hepatitis, cirrhosis of the liver, sarcoid, scleroderma, and pulmonary fibrosis. In most diseases, other than rheumatoid arthritis, the latex-fixation test (based on human gammaglobulin) is more often positive than the Rose-Waaler reaction (based on rabbit gammaglobulin).

Antinuclear factor and positive L.E. tests are found in some cases of rheumatoid arthritis. Systemic lupus erythematosus rarely develops in these patients, but they tend to have somewhat more severe disease with a raised incidence of arthritis.

Though the arteritis involves digital and visceral vessels, and the peripheral neuropathy is attributed to it, renal damage is rare. The affected joints in rheumatoid arthritis show infiltration with lymphocytes, histiocytes, and sometimes plasma-cells, and the formation of lymphoid follicles. Pannus is formed and there is erosion of cartilage. These changes can all be produced by implanting particulate (insoluble) antigens into the joints of animals; streptolysin S of the streptococcus has a similar effect. These findings raise the question of whether the human disease is due to the presence of antigenic material in the joints, and there is current interest in the possible role of mycoplasma and other micro-organisms.

Sjögren's Disease presents as failure of secretion by the lacrimal and salivary glands, and it is often associated with rheumatoid arthritis. It is of considerable immunological interest, because organ-specific antibodies against intralobular salivary-gland ducts can be demonstrated by immunofluorescence, while non-organ-specific antibodies, which react with nuclear and cytoplasmic cell components, often occur. In some patients the clinical picture merges with that of systemic lupus erythematosus.

Dermatomyositis.—Some types of dermatomyositis may belong to the systemic lupus erythematosus group of diseases. Antinuclear factor is sometimes found, and the disease may develop features of systemic lupus erythematosus. In adults there is a frequent association with carcinoma.

Miscellaneous Conditions

Liver Disease.—Patients with infectious hepatitis often have antibodies against altered gammaglobulin (positive latex test) and complement-fixing antibodies against cytoplasm. This is an example of autoantibody formation caused by infection.

Cirrhosis of the liver and infiltration of the liver with lymphocytes is sometimes associated with minor manifestations of systemic lupus erythematosus, such as rashes and haemolytic anaemia. Many of the patients have positive L.E.-cell tests, and antinuclear factor, antibody against smooth muscle, and complement-fixing antibodies against cytoplasm are found. This disease, which is called lupoid hepatitis, responds to some extent to cortisone.

Primary biliary cirrhosis presents as jaundice simulating that of extrahepatic biliary obstruction. The vast majority of these patients have positive autoimmune complement-fixation reactions, often to very high titres. The antibody reacts with a mitochondrial antigen: this is useful in differential diagnosis, because antibodies against mitochondria are rare in extrahepatic biliary obstruction.

Multiple Sclerosis.—The ease with which encephalomyelitis can be produced in animals by immunization with brain in Freund's complete adjuvant has led to the suggestion that multiple sclerosis may be an autoimmune disease. The gammaglobulin in the cerebrospinal fluid, which is responsible for the positive colloidal-gold reaction, is raised. Recently autoantibodies have been demonstrated which damage myelinated cells in tissue culture; but similar antibodies occur in motor-neurone disease, and these particular autoantibodies may be the result rather than the cause of tissue damage.

Carcinomatous Neuropathy.—Carcinoma, especially oat-cell carcinoma of the bronchus, is often associated with neuropathy which is not due to local metastases. Antibodies against the nerve bodies of posterior-root ganglia and other cells are found in sensory carcinomatous neuropathy. Tumours sometimes secrete material which is not produced by the normal cells from which they are derived. The question arises whether the tumours associated with certain forms of carcinomatous neuropathy have an antigen similar to brain tissue and so cause autoimmune disease.

Peripheral Neuritis.—Autoantibodies against nervous tissues are found in about a quarter of patients with the Guillain-Barré syndrome of peripheral neuritis associated with high protein content but low cell count in the cerebrospinal fluid.

Pemphigus is characterized by Nikolsky's sign—that is, the stratum corneum can be easily separated from the underlying epidermis—which is the result of damage to the prickle-cell layer. Autoantibodies against these latter cells can be demonstrated by immunofluorescence.

Aphthous Ulcer.—Autoantibodies against buccal mucosa have been demonstrated by complement fixation and immunofluorescence.

Conclusion

Immunologists at the turn of the century were aware of the damaging effect of immune reactions, and they considered the possibility of autoimmune disease. Interest in autoimmune disease revived with the identification of autoimmune haemolytic anaemia and the detection of autoantibodies adhering to red cells with the help of antihuman gammaglobulin serum (Coombs test). Burnet's concept of immune tolerance indicated a special mechanism whereby animals do not produce antibodies against their own tissue components, and this implied that altered physiology might lead to autoimmune reactions and disease. Two sets of observations were historically important. Firstly, the discovery of the L.E. test and the demonstration of antibodies against nuclei in systemic lupus erythematosus; this provided an example of a multisystem disease associated with multiple autoantibody production. Secondly, the production of various autoimmune diseases, including encephalomyelitis and thyroiditis, by immunization with the corresponding organ in Freund's complete adjuvant, and the demonstration of autoantibodies in Hashimoto's disease.

Early interest was focused on the following factors:

(1) Were the antibodies found in putative human autoimmune disease true antibodies? In all cases investigated autoantibodies have been shown to have the physicochemical properties of antibodies, and they are found by methods used to detect antibodies. Rheumatoid factor was originally considered to be an exception because it is a macroglobulin; but it is now known that many antibodies, especially those produced shortly after immunization or in response to particulate antigen, are macroglobulins.

(2) Were the antibodies indeed autoantibodies and not isoantibodies reacting with antigens produced in some but not all humans, and not in the patient from whom the antibody was taken? With the exception of some of the rheumatoid factors, the initial view that an antibody was an autoantibody has proved to be correct.

(3) Is autoantibody or autoreactive delayed hypersensitivity responsible for tissue damage? Methods are not yet available to answer this question. It seems likely that in some situations both circulating antibody *and* cellular factors are important..

(4) Are autoimmune responses the cause or merely the result of tissue damage?

Despite the inability to answer the last two questions, and the unsatisfactory situation in which putative autoimmune disease is virtually synonymous with the discovery of an autoimmune system, current research interest is now centring on the mechanism of production of autoimmune responses.

Three of the lines of approach are (*a*) the role of antigens similar but not identical with self; (*b*) the role of micro-organisms, including mycoplasma and viruses; and (*c*) the role of the hydrolytic enzymes in the intracellular organelles called lysosomes, which are able to degrade normal tissue components.

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Fumes from Soldering

Q.—*What are the hazards of inhaling the fumes given off in the process of soldering?*

A.—Soldering processes include soft soldering and brazing (hard soldering and silver soldering). Brazing[1] is defined as "the making of a joint between pieces of metal, in which molten filler metal is drawn by capillary attraction into the space between the closely adjacent surfaces of the parts to be joined. In general, the melting point of the filler metal is above 500° C. and below that of the metal to be joined." Soldering is "a joining process similar to brazing but in which the filler metal melts at a temperature below 500° C."

Toxic fumes and gases are generated from the constituents of the filler metals, the fluxes, and the coatings on the metal surfaces. Generally speaking, hazards are likely to occur from poor technique and the overheating of the filler metal. The most common chemical contaminants of the toxic fumes and gases generated from different soldering processes are zinc, lead, cadmium, and beryllium from the filler metals and coatings on metal surfaces, and fluorine compounds, zinc chloride, rosin, methylated spirits, and isopropyl alcohol from the fluxes.

Chrome Ulcer of Nasal Septum

Q.—*Is it safe for a man with a healed perforated chrome ulcer of the nasal septum to return to work involving contact with chrome salts?*

A.—There is no reason why a man with a healed perforated chrome ulcer of the nasal septum should not return to work involving contact with chrome salts. However, a chrome ulcer of the nasal septum indicates that an employee has been exposed to unduly high atmospheric concentrations of chrome salts, and the situation should be investigated by air sampling and analysis so that preventive measures can be instituted.

The threshold limit value[1] for chromic acid and chromates (as C_2O_3) is 0.1 mg./m.^{3} (milligrammes per cubic metre).

Aetiology of Osteogenesis Imperfecta

Q.—*A healthy woman with one normal child has had a stillborn infant with severe osteogenesis imperfecta. What are the risks of future infants being affected by this disorder?*

A.—When neither parent has any evidence of osteogenesis imperfecta the risks of future infants being affected are small.

Osteogenesis imperfecta congenita has occurred on several occasions as an exceptionally severe manifestation in families with dominant osteogenesis imperfecta.[1] Most cases, however, are sporadic and are probably caused by fresh dominant mutations. In Seedorff's Danish series[1] one patient was born to a parent with osteogenesis imperfecta tarda and 6 were sporadic with 19 unaffected sibs. In Smårs's series for Sweden,[2] of the 22 cases born to unaffected parents 17 were sporadic and had in all 46 unaffected sibs, but the other 5 occurred in two non-consanguineous families, 3 in a sibship of 7, and the other 2 in a sibship of 2. In a third series of 15 consecutive cases from one hospital[3] one mother had blue sclerae and deafness and another mother blue sclerae alone, but it appears that no sib was affected. The total number of sibs, however, was not stated.

In addition to the families of Smårs there are a few convincing case reports of individual families with normal parents having two children or dizygotic twins affected by osteogenesis imperfecta congenita.[4 5] Other reports are not fully documented, and do not exclude a diagnosis of congenital recessive hypophosphatasia.

Inhalation of Starch Dust

Q.—*Is there any hazard from the inhalation of starch dust over a long period?*

A.—There is no evidence that the inhalation of starch dust over a long period gives rise to any health hazard.

Pox Scars

Q.—*Is there any effective treatment for scars resulting from smallpox or chickenpox?*

A.—Scarring results from destructive damage to the skin affecting not only the full thickness of the epidermis, including the accessory glands and hair follicles, but also of the corium. These changes are irreversible.

Scarring from chicken-pox or smallpox tends to produce slight superficial atrophy with depigmentation, which tends to become more conspicuous during the summer with tanning of the adjacent normal skin. It is rarely possible to improve such superficial scars by excision followed by grafting of normal skin. It is advisable to cover the whole affected area with some screening applications before exposure to intense sunlight. That will prevent disproportionate tanning of the normal skin and burning of the depigmented scars.

Hypertrophic and keloid scars can be flattened by infiltration with a 1% solution of triamcinolone, repeated if necessary at intervals of two to three weeks until the lesion is flush with the normal skin. It is then possible to camouflage any discoloration of the scar with proprietary applications like Covermark. This is usually more acceptable also for depigmented depressed scars than staining with potassium permanganate solution (1:8,000). Scars tend to become less conspicuous with the passage of time.

Treatment of Alopecia

Q.—*A preparation of live E. coli was recommended years ago in the treatment of intractable alopecia areata or even totalis. Was this preparation of use?*

A.—It is not surprising that in conditions for which specific treatment is not available, and which pursue an unpredictable natural course, widely different treatments have been claimed to be of value. There is no acceptable evidence that preparations of *E. coli*, live or dead, are beneficial in alopecia areata or totalis.

Ultrasonic Treatment for Varicose Ulcer

Q.—*Have ultrasonic rays any place in the treatment of a refractory ulcer?*

A.—Ultrasonic rays have a reputed ability to fragment local fibrous tissue. Their particular place is therefore in the management of the woody plaque type of induration in the lower leg that results from local "venous" fat necrosis and periphlebitis. This type of induration often effloresces into the full-blown venous ulcer lesion. Even so, results from this type of therapy have not been particularly rewarding. Compression, preferably over "Molefoam" pads, still forms the linchpin of management.

For the refractory ulcer lesion—presumably refractory to compression treatment—bed-rest in hospital and elevation of the limb are the proper answer. Antibiotic creams of all types are to be avoided. The ulcer should be repeatedly dressed with equal parts of eusol and liquid paraffin. This rapidly clears local sloughs and allows a rich granulation bed to form, for which small pinch grafts from the abdomen make a good cover.

Congenital Ichthyosis

Q.—*A patient who has congenital ichthyosis has noticed that whenever she has a course of tetracycline her skin stops scaling. Is there any explanation for this?*

A.—It would be relevant to know whether the patient has ichthyosis vulgaris or bullous ichthyosiform erythroderma. Both conditions are congenital and incurable, but, though they may have much in common clinically, secondary infection, with often inconspicuous pustules and bullae, is a feature only of bullous ichthyosiform erythroderma. The latter condition may benefit significantly from systemic treatment with antibiotics. Swabs from moist lesions, especially bullae and flexures, should identify the infecting micro-organisms.

Book Reviews

Urology

Encyclopedia of Urology. Vol. XI/1. Tumours I, by Arthur Jacobs and Eric Riches, Organic Diseases, by Leslie N. Pyrah. (Pp. 286+xii; illustrated. DM.128.) Berlin, Heidelberg, and New York: Springer. 1967.

Volume XI/1, the latest to appear in this important international work, deals with tumours of the kidney, ureter, and bladder, and also with a miscellaneous collection of unrelated urological conditions grouped under the heading of "organic diseases."

There have doubtless been good reasons for breaking the sequence on tumours and leaving the remainder to a future section (volume XI/2), but one effect which may well appeal to British readers has been to allow the whole of the present text to appear in English. Furthermore, notwithstanding the eminence of the contributors, the interpolation of additional material contrives to make this volume one of the most valuable and interesting in the series.

Writing on tumours of the kidney and ureter Sir Eric Riches ranges over their incidence and classification and refers to current aspects of aetiology. His exceptional clinical and surgical experience, supplemented by radiological and pathological studies at the Middlesex Hospital, provides an appropriate background for a critical review of treatment and prognosis. The importance of radiology in the detection of early tumours is suitably stressed and amply illustrated by photographs of surgical specimens superimposed on the *x*-ray films. Among the techniques discussed are nephrotomography and aortography but, though selective arteriography is mentioned, most of the illustrations depict the earlier translumbar technique. Of particular interest are the sections dealing with the grading and staging of parenchymal tumours in relation to prognosis, and details of a 10-year follow-up study are included. The excellence of the supporting microphotographs merits special commendation.

Tumours of the bladder, a subject of perennial interest to all urologists, are ably dealt with by Arthur Jacobs, whose facile style and wide acquaintance with the problems involved contribute to a well-balanced account. He is assisted by Professor Symington and his colleagues in a description of the pathology of the wide variety of neoplastic lesions which may affect the organ. Particular emphasis is again laid on the grading and staging of epithelial tumours as a guide to the selection of appropriate treatment, and the merits of surgery and radiotherapy are fully discussed. No mention is made of the instillation of cytotoxic agents, nor of recent work on chromosome analysis as a possible guide to tumour staging, but perhaps in each instance their present value is difficult to assess.

The remainder of the volume affords full scope for the peripatetic philosophy of Professor Pyrah with subjects ranging in descending order from infarction of the kidney to torsion of the testicle. Movable kidney, positional change of the bladder, foreign bodies, priapism, Peyronie's disease, and scrotal swellings are all matters on which urologists will welcome his expert guidance. Indeed his far-reaching and discriminating descriptions will be recognized as filling a gap which notably exists in many of the standard textbooks.

Throughout the volume, as in the case of its predecessors, a high technical standard of production is sustained. The wide range and quality of the contents redounds to the credit of British urology and should ensure pride of place in the library of all interested in the specialty.

J. D. FERGUSSON.

Misery in our Midst

Sans Everything. A Case to Answer. Presented by Barbara Robb on behalf of A.E.G.I.S (Pp. 148+xvi. 18s.) London: Thomas Nelson. 1967.

The small volume *Sans Everything* packs between its covers a horrifying story of the grim conditions in which many old people exist in hospital. The material for the book is a record of reports made to A.E.G.I.S. This association for Aid for the Elderly in Government Institutions has as its aim to shame the Government and people into doing something about the cruelty and neglect which is the lot of many of our aged citizens.

The first section of the book, "The Case," consists of a number of letters from nurses and social workers whose consciences have led them to protest, and an account of the life of an old lady in a mental hospital as observed by the authors. Some of the evidence suggests that the observers have failed to understand the way facts are distorted by patients suffering from mental disorder and the way relatives may project their own guilty feelings on to the institution. There is no attempt in the report to assess the frequency of callousness in the hospital service and little to assess its causes.

In spite of these deficiencies the authors succeed in stimulating the conscience of the reader and the book has undoubtedly drawn public attention to the problem. The danger is that the lack of facts may enable it to be too easily dismissed, for those who have worked with the aged know that there is some truth in the accusations. Most voluntary and hospital workers will know of geriatric institutions where the doctors bring nothing of modern medicine to the care of their patients, and where the nurses are more concerned about their authority and their concept of discipline than about understanding and kindness.

The second section of the book, "Some Answers," deals with the way in which the black spots might be eradicated. Priority is rightly given to a medical solution, because an unhealthy hospital cannot be cured until the medical staff have been converted, and the doctors are in the best position to teach new attitudes to the other staff. The administration of the psycho-geriatric service in Severalls Hospital, Colchester, is described with reference to admission procedure, month-in month-out system, day care, boarding out, and community support. Such a procedure is practised in the most progressive of the geriatric and psycho-geriatric departments in this country, but there are too few of them.

Mrs. Barbara Robb and Mr. P. G. M. Thomson then give details of their "Project 70," which is a self-financing scheme in which they propose that new townships should be built on huge, undeveloped estates of certain carefully chosen mental hospitals, and that the revenue from the family flats and houses of these self-contained communities and their shops, offices, and other premises could finance new accommodation for the elderly patients now in hospital. This is an attractive scheme, but its success would depend upon trained personnel, and these do not exist at present. A.E.G.I.S., however, urges the following measures should be taken at once to remedy this:

(1) Provision of courses for young registrars to train as consultants.

(2) Provision of training course for geriatric nurses and recognition of their status and the establishment of a register, such as already exists for midwifery. The inclusion of more training in the care of the elderly in nurses' general training.

(3) The organization of voluntary help.

(4) The adoption of such methods as are used at Severalls and other progressive departments.

In another chapter Professor Brian Abel Smith discusses an administrative solution, that of a "Hospital Commissioner." While he accepts that the National Health Service has already improved the situation, he argues that in hospitals where interpersonal relationships, staffing, buildings, and amenities are poor in quality and quantity these bad conditions and attitudes perpetuate themselves. He suggests that "new recruits, whether medical, nursing, or domestic, either accept the institution as it is or find a job elsewhere. Very few stay to fight for what they know is right. The vast majority protest only by leaving. Those who cannot leave are the patients with nowhere else to go." Professor Abel Smith's suggestion that a hospital commissioner should be appointed who can enforce better standards in the hospital service is unrealistic, and would not have been suggested had the author attempted a more detailed diagnosis of the trouble. It is well known throughout the British medical service, and indeed in medical services in other countries in the Western world, that geriatrics is not attractive to medical or nursing recruits, except for a dedicated minority. To commence a series of disciplinary actions would aggravate the problem by making geriatrics even less attractive and driving the staff into closer defensive attitudes. What is required is an investigation into the causes of the inferior status of geriatrics so that these may be changed. Some of the special troubles include the desperate state of the buildings in which old people are nursed, the low level of medical and nurse staffing, the poor co-operation that so often exists between the hospitals and the welfare services, and the failure to separate mentally and physically ill old people and treat them in appropriate hospitals. These disorders, and others, are clearly described in the book, but the opportunity to present constructive reforms is not taken.

Change will come about only if the public conscience is effectively aroused. Dr. M. D. Enoch, postgraduate clinical tutor at the University of Birmingham and consultant psychiatrist to the Shrewsbury Hospital Group, in the last chapter of the book, "Ready for the Scrap Heap," summarizes the situation: "The elderly, increasing in numbers year by year, are a group of people who do not fit into the materialistic plan of this present affluent society. From the politicians' point of view they must be seen as a group who do not constitute any form of pressure group. The greater number of them anyway would not be able to creep to the polling booths. A great number of them cannot even write an awkward letter of protest to the press or anybody else, and anyway they have their pride. It might be said that we have provided for them, but can we really expect them to choose the role of public beggars ? "

It is surely impossible for anyone who reads this book not to feel some personal responsibility for the sufferings of the defenceless which it describes.

Nucleic Acid Research

Progress in Nucleic Acid Research and Molecular Biology. Vol. 5. Edited by J. N. Davidson and Waldo E. Cohn. (Pp. 450+xvii; illustrated. £6 8s.) New York and London: Academic Press. 1966.

In 1960 appeared the last three volumes of *The Nucleic Acids: Chemistry and Biology*, edited by Chargaff and Davidson. Progress in this field was so rapid that it was widely welcomed when the present authors published in 1963 the first two volumes of their series *Progress in Nucleic Acid Research.* The fifth volume, which carries the additional and fashionable label "Molecular Biology," again fully demonstrates the enormous progress in this area of endeavour, and it will be gratefully received by those who are unable to follow the very numerous single publications in many journals.

The editors have assembled contributions particularly about unusual or altered nucleosides. These are sometimes referred to as "minor" nucleosides, but this qualification is used only in the quantitative sense, and, as the editors point out, it does not in any way indicate a lack of importance. There are chapters on pseudouridine, which was discovered as recently as 1957 and is found in the transfer R.N.A. of many organisms, and an exhaustive discussion of the D-arabinosyl nucleosides, which are associated with sponges and metabolized by bacteria. The relative lack in animal cells of a deaminase acting on arabinonucleosides has permitted the demonstration of the considerable effect of such compounds on, for example, leukaemic cells in culture. This toxicity manifests itself primarily in an inhibition of D.N.A. synthesis.

There are now known numerous nucleoside antibiotics. They include purine nucleosides such as puromycine, pyrimidine nucleosides, and compounds such as septacidin, which contain a carbohydrate moiety linked glycosylically to adenine, and other related molecules. One chapter records the effects of some chemical mutagens and carcinogens on nucleic acids. Nucleoproteins are attacked by mustard gas by way of alkylation of their guanine moiety. A great deal is known now about chemical carcinogens alkylating nucleic acids in vivo. Collagen is unique among proteins for its high content of hydroxyproline and hydroxylysine. In view of recent work on methylation of nucleic acid by alkylating reagents it seems reasonable to postulate the possible existence of lysine and proline hydroxylases acting in a similar fashion on proline and lysine in the preformed polymer.

The discovery of D.N.A. in the chloroplasts of algae and higher plants has produced evidence that there is D.N.A. in mitochondria of animal cells. It is thought that the cell contains various kinds of autonomous organelles with their own genetic D.N.A. One chapter is devoted to chloroplast D.N.A. and to the extranuclear D.N.A. in *Chlorella,* which provides evidence for the existence in cells of "metabolic D.N.A." in addition to the "genetic D.N.A." Another review deals with the different ways in which hormones affect the metabolism of all types of R.N.A., and thereby control utilization of R.N.A. for protein synthesis. The recombination of D.N.A. molecules is discussed thoroughly. It is of fundamental importance for the understanding of D.N.A. genetics. It seems likely that genetic or molecular recombination is based on the interaction of complementary polynucleotides, and it is concluded that freely recombining D.N.A. molecules must be assembled from nonrepetitive short lengths.

This volume is full of interest not only for the molecular biologist—for whom the numerous references will be invaluable—but will also appeal to a much wider circle of biologists, and in fact to all those who are concerned with the living cell.

H. LEHMANN.

Advice for First Aiders

First Aid in the Factory. 3rd edition. By Lord Taylor, B.Sc., M.D., F.R.C.P. (Pp. 150+ix; illustrated. 12s. 6d.) London: Longmans, Green. 1967.

The first aid described by Lord Taylor for the guidance of factory workers is well conceived and includes a good deal of treatment that, though simple, is in fact definitive. He makes a good case for this interpretation and is careful to remind his readers that they must know when to stop.

The sections on wounds and bleeding are admirably clear and sensible, but it is regrettable that although the author refers to its "mythology" his loose use of the word "shock" is less likely to clarify the subject than would entirely abandoning the word. After the introductory remarks about splintage it is disappointing to find how much of it is recommended for use on the upper limb and more disappointing to find that inflatable splints are not even mentioned. It is hard to see the justification for devoting space to a detailed description of the obsolete methods of ventilating the lungs artificially. There is no mention of the airways that have been recommended for use with artificial ventilation ; if this is because they are not favoured, the reasons for this would have been worth reading.

In spite of the critical note of the foregoing, the points mentioned occur in a large amount of admirable advice. At the present rate, the fourth edition will soon be due and it could usefully contain references to injection injuries, overbreathing tetany, and thumping the sternum and raising the legs to restore the heartbeat.

P. S. LONDON.

Tropical Diseases

Tropical Diseases. 2nd edition. Supplement to *The Principles and Practice of Medicine.* 8th edition. By Frederick J. Wright, M.A., M.D.Cantab., F.R.C.P.Ed., F.R.C.P.Lond., D.T.M.&H.Eng., and James P. Baird, M.D., F.R.C.P.Ed., F.R.C.P.Lond. (Pp. 176+viii; illustrated. 10s. 6d.) Edinburgh and London: E. & S. Livingstone. 1967.

The supplement to *The Principles and Practice of Medicine* will be useful only to persons who already own or intend to buy this textbook of medicine, since such important tropical diseases as malaria and amoebiasis are deliberately left out.

The text is 171 pages long and contains sections on diseases due to protozoa ; diseases due to bacteria, spirochaetes, and spirilla ; diseases due to viruses and rickettsiae ; diseases due to helminths ; diseases due to fungi ; micellaneous conditions ; and anaemia in the tropics. The text is clearly and concisely written, with the sections on treatment remarkably up to date. In view of the diminishing importance of yaws possibly less space need be devoted to this subject in the future, while the beneficial effect of niridazole in the treatment of guinea-worm infection should be mentioned. Most pathologists would not accept malaria as an aetiological agent in cirrhosis of the liver.

It may be wiser in future editions of the main textbook of medicine to include the contents of this supplement in it rather than to produce it as a separate and incomplete entity.

H. M. GILLES.

Mental Health

Mental Health and Contemporary Thought. Vol. 2 of Report of World Federation for Mental Health. Edited by Kenneth Soddy and Robert H. Ahrenfeldt. (Pp. 362+xxix. 55s.) London: Tavistock. 1967.

Mental Health in the Service of the Community. Vol. 3 of Report of World Federation for Mental Health. Edited by Kenneth Soddy and Robert H. Ahrenfeldt. (Pp. 306+xxvii. 45s.) London: Tavistock. 1967.

These two volumes are numbers 2 and 3[1] of a report of a conference held in 1961 by a study group of the World Federation of Mental Health. It surveyed the field of mental health from the point of view of various disciplines. Accordingly, though psychiatrists predominated, anthropology, social psychology, education, and personnel research were also represented.

---

[1] For review of Vol. 1 see *Brit. med. J.*, 1966, 1, 407.

As might be expected, a wide range of topics are discussed. Volume 2 deals with problems brought about by changes in social structure; individual aggressiveness and war; the definition of "mental health" and professional training and education for workers in this field. Volume 3 is concerned with the recognition of mental disorders, the setting up of psychiatric services, and future research.

The approach has to balance breadth of vision with depth of focus, knowing that whatever balance is struck it will not please everybody. In these volumes an enormous number of interesting issues are raised, but they are discussed with a ponderous superficiality which makes frustrating reading. Though the original contributions to the conference may well have been stimulating, their impact has been muffled by the mists of time and an editorial style which tends to start paragraphs with redundant phrases such as "it appears to have become much more generally accepted that" or "it can hardly be doubted that." Each volume has a useful and extensive bibliography to the subjects covered in all three books.

For their comprehensiveness these volumes will be of value to readers interested in mental health, but they are unlikely to inspire many enthusiastic new recruits. They should be compulsory reading for future editors of multidisciplinary conferences.

J. L. T. BIRLEY.

Books Received

Review is not precluded by notice here of books recently received.

Historic Derivations of Modern Psychiatry. Edited by Iago Galdston, M.D. (Pp. 241+xiv; illustrated. £5 0s. 6d.) London: McGraw-Hill. 1967.

Social Work with the Mentally Subnormal. By Joan Todd. (Pp. 86. 15s.) London: Routledge & Kegan Paul. 1967.

Principles and Practice of Obstetric Analgesia and Anesthesia. Vol. 1. Fundamental Considerations. By John J. Bonica, M.D. (Pp. 837+xvi; illustrated. £9 15s.) Oxford: Blackwell. 1967.

Principles of Clinical Electrocardiography. 6th edition. By Mervin J. Goldman, M.D. (Pp. 394; illustrated. 45s.) Oxford: Blackwell. 1967.

Notes on Medical Virology. By Morag C. Timbury, M.D., Ph.D., M.C.Path. (Pp. 106+vii; illustrated. 10s. 6d.) Edinburgh and London: E. & S. Livingstone. 1967.

Outline of Orthopaedics. 6th edition. By John Crawford Adams, M.D., M.S., F.R.C.S. (Pp. 467+vii; illustrated. 40s.) Edinburgh and London: E. & S. Livingstone. 1967.

Principles and Methods of Social Psychology. By Edwin P. Hollander. (Pp. 520+xxiii. 64s.) London: Oxford University Press. 1967.

Pathology of Laboratory Rats and Mice. Edited by Ernest Cotchin, D.Sc., F.R.C.V.S., F.C.Path., and Francis J. C. Roe, D.M.(Oxon.), D.Sc., F.C.Path. (Pp. 848+xxiii; illustrated. £7 15s.) Oxford: Blackwell. 1967.

Radio-Diagnostic en Rhumatologie. By Stanislas de Sèze, Micheline Phankim-Koupernik, et les médecins du Centre de Rhumatologie Viggo Petersen. (Pp. 479; illustrated. No price given.) Paris: Expansion Scientifique Française. 1967.

Clinical Psychopathology. Signs and Symptoms in Psychiatry. By Frank Fish, M.B., M.R.C.P., M.R.C.P.Ed., D.P.M. (Pp. 120+vii. 30s.) Bristol: John Wright. 1967.

Laboratory Diagnostic Procedures in the Rheumatic Diseases. Edited by Alan S. Cohen, M.D. (Pp. 363+xii; illustrated. £5.) London: J. & A. Churchill. 1967.

A Primer of Pathology. 2nd edition. By F. A. Ward, L.R.C.P.I., M.C.Path. (Pp. 116+viii. 22s. 6d.) London: Butterworth. 1967.

Aspects of Drug Addiction. By Martin Silberman. (Pp. 112. 7s. 6d.) London: Royal London Prisoners' Aid Society. 1967.

Communicating with the Patient. By P. Ley, B.A., Dip.Psych., and M. S. Spelman, M.B., Ch.B., D.P.M., M.D. (Pp. 128. 37s. 6d.) London: Staples. 1967.

Phase Contrast and Interference Microscopy for Cell Biologists. By K. F. A. Ross, D.Phil. (Oxon.). (Pp. 238+xxi; illustrated. 70s.) London: Edward Arnold. 1967.

Surgery for Nurses. 11th edition. By James Moroney. (Pp. 803+xii; illustrated. 45s.) Edinburgh and London: E. & S. Livingstone. 1967.

Penguin Science Survey 1967. The Biology of Sex. Edited by Anthony Allison. (Pp. 288; illustrated. 12s. 6d.) Harmondsworth, Middlesex: Penguin. 1967.

Introducing Biology. By James F. Riley. (Pp. 154; illustrated. 4s. 6d.) Harmondsworth, Middlesex: Penguin. 1967.

Fonctions Endocriniennes de l'Ovaire. Vol. 2. Symposium, directed by M. F. Jayle. (Pp. 212–634; illustrated. No price given.) Paris: Gauthier-Villars. 1967.

Recent Research on Gonadotrophic Hormones. Edited by E. Trevor Bell, B.Sc., Ph.D., and John A. Loraine, D.Sc., M.B., Ph.D., F.R.C.P.Ed. (Pp. 345+ix; illustrated. 70s.) Edinburgh and London: E. & S. Livingstone. 1967.

Vascular Histochemistry. By C. W. M. Adams, M.A., M.D.(Camb.), D.Sc.(Lond.), M.R.C.P. (Lond.), M.C.Path. (Pp. 448; illustrated. £6.) Lloyd-Luke. 1967.

Practical Paediatric Problems. 2nd edition. By James H. Hutchison, O.B.E., M.D.(Glasg.), F.R.S.E., F.R.C.P.(Lond.), F.R.C.P.(Ed.), F.R.C.P.(Glasg.). (Pp. 559+xv; illustrated. 55s.) London: Lloyd-Luke. 1967.

Vision and the Eye. By M. H. Pirenne, Dr.Sc., Ph.D., M.A. (Pp. 224+xvi; illustrated. 50s. Paper 25s.) London: Chapman and Hall. 1967.

Pränatale Erkrankungen des Menschen. By Professor O. Thalhammer. (Pp. 442+ix; illustrated. DM. 78.) Stuttgart: Georg Thieme. 1967.

MEDICAL HISTORY

International Congress of Medicine 1867 and Some of the Personalities Involved

W. H. McMENEMEY,* D.M., F.R.C.P., F.C.PATH.

Brit. med. J., 1967, 3, 487–489

The International Medical Congress of 1867, the first of its kind, was held in Paris from Friday 16 August to Wednesday 28 August. The idea to hold such a gathering to coincide with the Paris exhibition was advanced by Professor Henri Gintrac, of Bordeaux, during the third annual French medical convention held in that city in the year 1865. Though the project was warmly received in France the *British Medical Journal* (1867, 1, 610) feared that the organizers were leaving much undone if they wished it to be truly international: they had, for instance, omitted to invite societies, colleges, and "distinguished personages," so that "the few Englishmen who attend will probably be chiefly excursionists, representing themselves." It is possible, however, that some of the invitations were left in the hands of "the foreign delegates" appointed by the Congress Bureau—Dr. Hermann Beiget, Berlin graduate and physician to the Metropolitan Free Hospital in London, having been one of them. Thus while the only learned societies in the United Kingdom to be represented were the British Medical Association and the Medical Society of London there were no fewer than 18 from the United States. Belgium, France, Holland, Prussia, and Russia were each allocated an honorary member, while Portugal had two: the individual selected for France was the minister of public instruction. Most of these countries and also Bavaria sent a government delegate. Six vice-presidencies went to France and six to other countries, but this time the United Kingdom was represented, in fact by Mr. Victor de Méric, a Glasgow graduate of French origin and fashionable genitourinary surgeon, of 17 Brook Street, London W.1, who found himself in the distinguished company of the great Professor Virchow and Baron Larrey,[1] surgeon to the Emperor Napoleon III. He had done his best to advertise the congress among British doctors and in the columns of the *Lancet,* whose correspondent he was.

Visitors from Overseas

The reputation of La Manche was such as to deter many who otherwise were prepared to follow their portmanteaux on the boat and through *la douane* and the vicissitudes of the railroad journeys: but there were enticements, including a 50% reduction on the ordinary tariff, generously offered by the Compagnie du Nord, thanks to the kind offices of M. de Rothschild, director, and M. Cousin, "chef d'exploitation." Even so, there were "far more Cossaques than English present." At the Congress, de Méric recognized half a dozen London men, and there could have been a few from the country; but he was saddened to find that no one from Great Britain had been chosen to speak in the section on tuberculosis. In fact, there were 72 "adherents" from the United Kingdom, including Lionel Beale, Burney Yeo, Morell Mackenzie, and 25-year-old Robert Cowie, of Lerwick, one-time surgeon at the Fort Charlotte gaol, and then Medical Officer of Health to the Sumburgh Head and Whalsey Skerries Lighthouse, who proposed to address them on the subject of "prolonged menstruation in the Shetland Islands, and its relation to longevity." Dr. Cowie's name, however, appears on a list of authors who had not made the *acte d'adhésion* because their *mémoirs* had not complied with the conditions of the programme.

The only active participants from the British Isles were in fact Victor de Méric, Charles Drysdale, of the Metropolitan Free Hospital, and John Z. Laurence, of 30 Devonshire Street, surgeon at St. Bartholomew's Hospital, Chatham, and at the Southwark Eye Hospital, who presented a case of traumatic aneurysm in the orbit cured by ligation of the common carotid artery. Dr. Edward Tilt, a graduate of Paris and consulting physician to the Farringdon General Dispensary and Lying-In Chārity, an authority on female hygiene, was to have read a paper, but in his unavoidable absence it was presented by Dr. Ball, an Englishman naturalized and practising in Paris, and one of the secretaries of the congress. The ruling of *le Bureau* that "long papers will be deposited in the Acts of the Congress" could be interpreted either as an incentive to authors or perhaps as a deterrent.

There were 60 adherents from the United States, seven from Canada, one from the State of Kentucky, and one from the State of California.[2] There were 333 "founder" members, all Frenchmen, and 300 student tickets were issued, so the total number crowding into the amphitheatre of the School of Medicine sometimes amounted to 1,200 (one report says over 1,500). The flags of many nations decorated the hall, the bare walls of which were clothed with green baize and golden fringes. The "hemicycle" reserved for special dignitaries exhibited "a grand display of red velvet." The president and officials sat in gilt armchairs, but the congressists had to put up with hard benches. As one reporter declared, it was after all but a huge schoolroom. It appears to have been an intensely hot one too.

Patrons

Professor Jean Baptiste Bouillaud, of the Faculté de Paris and consulting physician to the Emperor, presided and Dr. Jaccoud was the general secretary. Others who patronized the congress were Professors Rokitansky, Wertheim, Friedreich,

---

* Professor of Pathology, Institute of Neurology, London W.C.1; Pathologist, Maida Vale Hospital for Nervous Diseases, London W.9.

[1] Baron Félix-Hippolyte Larrey was the same age as the Emperor, having been born in the year 1808. His distinguished father, Baron Dominique Jean Larrey (1766–1842) had been surgeon-in-chief of the Grande Armée and a personal friend of Napoleon Bonaparte.

[2] Although these states were listed separately they were admitted to the Union in 1792 and 1850 respectively.

Dr. Robert Cowie · Ernest Hart · Prof. Jaccoud · Victor de Méric · Dr. Ph. Ricord · Dr A. Robin

Some of the participants in the Congress.

Fallot, Robin, Broca, Tardieu, Vidal, Hughes Bennett, and William Stokes, and Dr. Inman, of Liverpool, but how many of them actually attended and paid their 20 francs it is not possible to say.

In his inaugural address the president spoke of his city with considerable warmth, even going so far as to quote from Casimir Delavigne—"La France, c'est Paris, et Paris c'est le monde." He welcomed them all, and without wishing to be profane believed their congress could be regarded as a *concile médical oecuménique.* People, he said, were travelling more and frontiers and physical barriers, including the Atlantic ocean, were counting for less and less. He reminded them that there had been an isolated medical congress in Paris in the year 1845.

Evidently the atmosphere at first was formal and frigid, but after the first few sessions it became less stiff. The congress was conducted entirely in French, and this was the reason why Dr. Cowie's paper was declined. Mr. de Méric seems to have spoken well and made a good impression. It was he who presented the report of the Harveian Society on the prevention of venereal disease, the committee, consisting of Tilbury Fox, Henry Maudsley, Victor Bazire, Beigel, Drysdale, and himself, having being set up after the passing of the Contagious Diseases (Amending) Act of 1866. Nevertheless de Méric, one-time Jacksonian Prize essayist, in a speech on the control of "une maison de tolérance de Londres," did not find favour with the reporter of the *British Medical Journal,* who doubted if "this very meritorious specialist and syphilographer" appreciated the sentiments of his adopted country. No respectable doctor could allow himself to be the servant of a brothel-keeper for purposes of allowing women to continue in sin.

Incidents

In general the meetings seem to have been quiet and amicable, but there were a few incidents. The first was when Dr. van Lohe, of Amsterdam, complained that the presentations thus far had been but a series of pathological lectures, and he demanded that the meeting forthwith proceed to a discussion of the many practical problems concerned with tuberculosis. But he was overruled by the president, who said that the programme had been sent out well in advance for all to see and that they would keep strictly to it. Another incident occurred when Professor Palasciano, of Naples, boasted that the legal status of members of the medical profession had vastly improved since Italy had become a free country. No longer were they bound, as in other European countries including France, to inform on their patients when, in the course of their professional duties, they learned that they were treating lawbreakers. This evidently upset the president and other Frenchmen too, but the Italians were left in no doubt that any French doctor would rather himself break the law than inform on his patient. An anxious Professor Bouillaud closed the proceedings as soon as he could, pointing out that such questions as they were discussing could not be raised in open meeting without the express permission of the French Government, and such permission would almost surely not be given.

The most dramatic incident, however, was when a tall grey-headed gentleman stood up and proclaimed in a loud voice, "Je suis médecin, syphilisé, et je me porte bien." This arose in the course of a most heated argument between Dr. Auzias-Turenne, who was recommending repeated inoculation as a means of rendering a prostitute resistant to the disease, and Professor Ricord, the chairman of the meeting and a vice-president of the congress, who was utterly opposed to the idea. The chairman, who "boiled with indignation," chided Dr. Auzias-Turenne for not having, like others, experimented on himself if he had faith in his claim. M. Crocq, of Brussels, apparently in an attempt to quieten the meeting, asked facetiously if it was expected of him, the official delegate of his country, to return and advise his government to syphilize all Belgians. A much applauded moment seems to have been when Dr. Lombard, of Geneva, in a discussion on the effects of climate on health, ended by shouting, "Death to malaria !"

Perhaps the most eagerly awaited of the speakers was Dr. Brown-Séquard, who was due to discuss the early signs of cerebral disease ; but, alas for his many admirers, the sudden illness and death from a ruptured aneurysm of the basilar artery of his young former colleague and fellow Mauritian Victor Bazire, assistant physician at the National Hospital for Epilepsy and Paralysis, had called him to London.

Social Occasions

Between two and three hundred attended the banquet which was held at the Grand Hotel, Professor Virchow being placed on the president's right. One of the speakers was Dr. Ernest Hart, editor of the *British Medical Journal,* who hoped that one day such a congress would be held in London. In the course of the evening the president broke the news of the death that morning of Professor Alfred Armand Louis Marie Velpeau, who with great distinction had held the chair of clinical surgery in Paris for 32 years. The request that the Congress should attend at his funeral was "carried by universal acclamation." The death of this man, who was regarded as the king of French surgeons, so soon after that of the great Armand Trousseau (23 June), cast a gloom over the whole congress.

Social occasions seem to have been few, but Dr. Marion Sims, who in the summer of 1862 had left New York and the hospital he had founded, on the *Great Eastern* with a return ticket, laid on "brilliant hospitality" at his handsome residence in the rue du Faubourg St. Honoré which, said one reporter, redounded greatly to the credit of America. In his short time in Paris his gynaecological prowess had brought him wealthy patients and important friends, including the Duchess of Hamilton, the Empress Eugénie, and the Emperor himself. He was in fact a familiar figure in Paris society and at Baden-Baden, and had even enjoyed the entrée to St. Cloud.

Success and Failure

According to the many accounts of this congress it proved a success if only for the reason that the French organizers had brought together men of different nations. But this success was deemed to be due entirely to the guests, because many of the leaders of French medicine did not attend and hospital officials were *en vacances.* It failed because the programme was rigid and did not provide sufficient time for discussion and because it was intelligible only to those fluent in the French language. This must have been the reason for the regrettable and "too absolute silence maintained by a number of the most distinguished of our countrymen" (*Brit. med. J.*, 1867, 2, 259). It failed most of all because apart from the banquet there was no opportunity for doctors to meet each other outside the amphitheatre. No reading-room, lounge, or refreshment room had been provided ; nor was there an official reception. There was, in fact, "an entire absence of hospitality, or even of public courtesies" (*Brit. med. J.*, 1867, 2, 254): this particular censure may well have been provoked by the unfortunate mismanagement of a banquet intended for medical journalists, to which the editors of almost all the principal journals "were forgotten to be invited." We are told that several Paris journalists, presumably also overlooked, regarded the congress as a comparative failure.

Nevertheless the topics seem to have been well chosen, and some of them, like the control of venereal disease, pointed a way which led eventually to the formation of the World Health Organization. Other subjects to engage the attention of members were postoperative accidents and the acclimatization of Europeans in the tropics.

An early report in the *Lancet,* as if to upbraid its readers for failing to support the congress, dwells on the amenities of Paris, adding "neither are English taverns wanting." But unfortunately this first of international medical gatherings was held near the time of the Annual Meeting of the British Medical Association and that of the British Association, which together attracted most of the doctors given to travel, and it is certain that Dublin and Dundee provided all necessary entertainment as well as good scientific fare.

Marion Sims, a native of South Carolina and a naturally happy man, was distressed by the Civil War, and it was during these sad years that his love for Europe matured. Thereafter he led a somewhat restless life between the two continents, spending the greater part on this side of the Atlantic, where, as he was prepared to admit, the wealthy patients were more likely to be found.

Victor de Méric, when he returned to London, would have been pleased to find that the correspondent of the *Edinburgh Medical Journal,* who seems to have been Professor J. Hughes Bennett, had praised him for his part in the scientific meetings. As surgeon at the Royal Free, German, and French Hospitals he seems to have been a busy man. He was also a corresponding member of the Imperial Medical Society of Lyons. He later moved from 17 to 52 Brook Street, and was eventually joined in practice by his son, who had qualified in 1871. He died in 1876 at the age of 65, and the obituary notice in the *British Medical Journal* described him as a genial man and an honourable character.

Robert Cowie published his paper, which in effect had been his graduation thesis, in response to the request of a Danish doctor who had read an abstract of it in *L'Union Médicale* and was interested in the subject. It was therefore incorporated in a short history and account of the Shetland Islands published by Cowie in 1871. It includes a description of an epidemic of "epilepsy" in women churchgoers some fifty years earlier on days when the weather was warm and the preacher "pathetic." The distressing fits, often accompanied by dismal cries and fixation of the eyes, were attributed to superpolarity of the nervous system resulting from religious fervour. When, however, the ingenious minister announced a new form of treatment for this distemper, to consist of immersion in the fresh-water loch facing the kirk, no further case occurred.

Cowie, a tall, powerful man, had received his medical training in Aberdeen and Edinburgh, and had joined his father in practice shortly before the latter's death in 1866. He was well liked by everybody and held many public appointments, including that of Inspector of Lemon Juice for the Northern District of Scotland and honorary surgeon to the 1st Orkney and Shetland Rifles. A few days after revising the second edition of his charming little book he developed symptoms of acute inflammation of the bowels, and 26 hours later, on 1 May 1874, died, greatly lamented, at the early age of 32. Through this tragic death the island crofters lost a fine friend and the profession a geographically isolated member who had been ready to play his humble part in representing his colleagues at the First International Congress of Medicine.

The photograph of Victor de Méric was supplied by the Royal College of Surgeons of England. We are indebted to Mr. E. J. F. Clausen, Shetland Islands, for supplying the picture of Dr. Robert Cowie.

IS THERE AN ALTERNATIVE?

A suggestion that is frequently made is that a quinquennial system of finance for the Health Service would greatly increase financial flexibility. This system has now been in operation for the universities for almost 80 years, and in his article below Mr. Alexander McWilliam discusses some aspects of its history and working.

Yearly or Quinquennial Grants?

A. McWILLIAM,* B.A., A.I.M.T.A.

Brit. med. J., 1967, 3, 489–491

An earlier article in this series examined the suggestion of taking medicine out of politics by creating a public corporation.[1] Keeping universities out of politics has been a matter of concern since they first received State support, and a unique system of grants-in-aid has been evolved to achieve this aim. In fact the University Grants Committee has been described[2] as "one of the most felicitous constitutional inventions of this century" and "characteristic British solution to a problem which many have thought to be logically insoluble, namely the combination of the benefits of State support for this branch of higher education with the benefits of an orderly freedom on behalf of the institutions subsidized."

Evolution of System

The Scottish universities were the first to receive support from public funds through Parliament. In 1831 they were placed on an annual parliamentary vote, and Parliament itself considered and decided academic issues. London was the first English university to receive grants, and was followed by the Welsh university colleges. From the start there were misgivings about State support for universities. The Treasury[3] held that

---

* Finance Officer, University of Durham.

"universities, as representing the highest intellect of the nation, should not be dependent on its politics. . . . The normal condition of a flourishing university should be one of independence and stability." In 1889 Parliament voted a total of £15,000 for the twelve university colleges of England and Scotland, while both the principle of State support and the national importance of the universities were accepted. At the same time a committee was formed to advise on how the grant should be distributed, the Treasury recommending that a review should be made every five years. This interval was regarded as sufficiently long to enable the university colleges to plan their finances, while allowing the committee and Parliament to take account of changes in the colleges' circumstances.

From the outset relations between the committee and the colleges were good: the colleges relied upon the impartiality of the committee, and the Treasury accepted the committee's recommendations for the distribution of the grant. The committee became a permanent advisory committee whose members were or had been university teachers, and M.P.s and active civil servants—who initially had been in the majority—were excluded. A practice of informal visits to universities grew up during which discussions were held with university staff and students as well as with their governing bodies. Within the total grant voted by Parliament on the committee's advice, the committee's recommended distribution to universities was not questioned. The grant received by each university was a block grant to be expended entirely at the university's discretion ; and the amount of the grant was fixed on a quinquennial basis.

University Grants Committee

The University Grants Committee was constituted in 1919, its principal terms of reference being "to inquire into the financial needs of university education in Great Britain ; to advise the Government as to the application of any grants made by Parliament towards meeting them." The 23 members of the Committee are appointed by the Secretary of State for Education and Science. The Chairman's is a full-time salaried post, and there are two part-time Deputy-Chairmen ; the 20 other members give part-time service. Academics have a majority: of the 18 members of the Committee (excluding the Chairman, the Deputy-Chairmen, and two members who assist only on questions connected with academic salaries), 13 are members of university staffs ; two members are engaged in other educational fields, and three in industry. Appointments are made for terms of five years, but members are often asked to serve a second term to provide continuity of experience.

The total grants in aid of universities for which the Committee is responsible now exceed £200m. There are two types of grants for which it is responsible—non-recurrent and recurrent grants.

Non-recurrent Grants

Non-recurrent grants are those given for specific purposes—for example, for buildings, furniture and equipment for new buildings, purchase of land and property, and architects' and other professional fees. The major expenditure relates to buildings—£42m. out of total non-recurrent grants of £69m. in 1966–7.

The universities tell the Committee of their individual building requirements and the priority they attach to them, together with estimates of cost. These are then examined by the Committee before it makes its recommendations to the Government. The next stage is that the Government considers these recommendations in the light of the general economic situation and determines the total available for building grants.

Normally the Committee will accept each university's view about the priorities in its own programme, provided it conforms with the Committee's general criteria. Nevertheless, the allocation for this type of grant is not a sum to be used at the university's discretion and if it cannot agree a detailed programme with the Committee the latter may transfer the allocation to another university's project.

Immediately after the second world war the allocation of non-recurrent grants was fixed year by year. This gave both the Committee and the universities only very short notice of their permitted programme. To plan a building both efficiently and economically requires time, and, moreover, the activities for which it is designed must be organized ; staff must be appointed, students admitted, equipment ordered and installed, and finance made available for these expenses. More recently, however, allocations have been determined for some years ahead—for example, at present they have been approved up to 1969–70. Thus, since the average time to complete a major building project is about two years, universities know reasonably accurately what new buildings will be brought into operation up to the end of the 1967–72 quinquennium.

Recurrent Grants

Recurrent grants to the universities are fixed for five years at a time, and on average amount to about 70% of current university expenditure. (The balance is met from a variety of sources —such as income from fees, endowments and benefactions, and grants from research councils.) Recurrent grant is a general contribution to university revenue, and except for relatively small grants earmarked to particular studies which the U.G.C. wishes to encourage (for example, business studies, Middle Eastern, Oriental, and African studies) is entirely at the disposal of the recipient university for teaching and research. The settlement for each university takes into account its expected development through the quinquennium, and is not re-examined unless Government policy is changed, such as the accelerated expansion which followed the Robbins report. Supplementary grants may be made to meet major increases in costs, such as approved increases in academic salary scales ; but in general each university has to make allowance for increased costs in determining its own budget. And certainly a university would not be able to have its grant reviewed simply because it had underestimated its financial needs.

The process for determining quinquennial grants starts with the visits paid to all universities by the U.G.C. during each quinquennium. The Committee meets various groups of staff and in this way it obtains first-hand knowledge of feelings and opinions in each institution. Conversely, the Committee also has an opportunity to explain its views of national needs and policies to the universities.

Each university subsequently submits estimates for the next quinquennium, distinguishing between existing commitments (the cost of which must not outrun its assured income) and proposed new developments. After considering and adjusting these the Committee then presents a case to the Government showing for each year of the quinquennium the amounts required both for existing commitments and for new developments, but not showing the requirements of individual universities. When the total amount decided by the Government is known the U.G.C. then has to consider its allocation to the universities. In notifying the universities about their grants the Committee normally also tells them about the general considerations which have influenced the allocation of the total sum. The convention is established that no major departure from the development programmes which have been discussed with the Committee should be made without consultation ; but there is no detailed control over the internal disposition of the grants in each university.

Universities are subject to a number of financial restraints: expenditure on academic salaries, which constitutes about half of the total recurrent expenditure, is controlled, since national salary scales are fixed by the Government ; the proportion of senior to junior posts is governed by agreed conventions ; and staff–student ratios in each faculty are important to the U.G.C.'s consideration of the quinquennial grant. Nevertheless there is a wide area within which each university is autonomous.

Advantages of Quinquennial System

Though the general pattern of its expenditure is determined in consultation with the U.G.C., the individual university decides the details of its annual budget without reference to any outside body. It alone is responsible for deciding where and when new posts should be established; what funds should be allocated to each academic department for teaching and research; how much should be devoted to the library; the relative merits of providing a theatre, or a sports hall, or supporting the local radio station. It can also decide whether to restrict expenditure now to provide for additional expenditure later, since the quinquennial system permits unspent balances to be carried forward from one year to another. Apart from the flexibility in planning that this method confers, it also militates against the ill-considered expenditure which sometimes results when funds are voted on an annual basis and unspent balances are cancelled at the end of each year of account. A spending department has little incentive to economy if it cannot expect to benefit from its savings; it may indeed fear that under-expenditure in one year may lead to its estimates for a later one being reduced to the same level. Consequently effort which might be more profitably applied is directed to making expenditure fit the estimate for an arbitrary period. Universities do not suffer this artificial constraint, and for the most part allow similar freedom internally—so that each academic department is free to carry forward unspent balances of the funds allocated to it for teaching and research purposes.

Over a period of nearly 80 years this system of finance has proved itself to be valuable both to the Government and to the universities. The quinquennial block grant, without any supplementation except for proved increased costs (and by no means all of these), is both an incentive to economy and a firm basis for forward planning. Universities were able to respond to the Government's request for rapid expansion of university places (following the Robbins report) because their development plans had been formulated already and policy decisions had already been taken—hence an acceleration of the programme was only a question mainly of administration. Finally, no evidence given to the Public Accounts Committee when the latter considered Parliament's control of university expenditure suggested a preferred alternative method of finance.

CONFERENCES AND MEETINGS

Dialysis and Transplantation

[FROM A SPECIAL CORRESPONDENT]

A change in emphasis in the regular dialysis programme seems inevitable following the meeting of the European Dialysis and Transplant Association in Paris (24–25 June) and the combined symposium with the Transplantation Society which followed it. At present the majority of effort in Britain and on the Continent is directed to hospital dialysis, but the demands on staff are enormous. In 81 centres answering the European Dialysis and Transplant Association questionary 621 patients were receiving regular haemodialysis; on average every 10 patients occupied the full-time services of six nurses and three doctors. The future role of the hospital unit as a training centre for home haemodialysis and a support for the transplantation centre was delineated during the conferences.

Home Haemodialysis

W. **DRUKKER** (Amsterdam) reported that six European centres were already operating home haemodialysis schemes and others were about to start. Other workers, including S. **SHALDON** and R. A. **BAILLOD** (London) and D. D. **HILTON** (Birmingham), reported success with this technique, showing that both mortality and morbidity were lower than in the hospital, while staff time was also reduced. An important element in the success of home haemodialysis has been the elimination of routine blood transfusion. P. J. **VERROUST** and R. E. **CROCKETT** (London) reported experience totalling 67 patient-years without transfusion except to replace acute blood loss or to relieve symptoms, which became incapacitating when the erythrocyte packed-cell volume had fallen to about 15%. Over 90% of their patients had been found to maintain an acceptable packed cell volume without regular "topping up," provided blood sampling was kept to a minimum and the Kiil dialyser was efficiently washed out.

The arteriovenous shunt remains one of the bugbears of regular dialysis. G. J. A. **CLUNIE** (Edinburgh) had found that nearly all infections of the shunt were due to staphylococci, the majority originating in the nares or other carrier sites of the patient. Prophylactic antibiotics did not prevent infection, but hexachlorophene bathing and local treatment of the nares had proved moderately effective. The use of streptokinase to free clotted cannulae was reported by D. C. **ANDERSON** (Edinburgh) and C.-M. **KJELLSTRAND** (Lund); when followed by anticoagulant therapy it prolonged the life of half the cannulae by more than a month. Prednisone was given to prevent systemic reactions. The possibility of a new shunt site in the upper thigh was opened up by a technique described by J. **HOELTZENBEIN** (Münster), who had used an all-Silastic prosthesis.

An alternative to the arteriovenous shunt, applicable only to hospital dialysis, is the Cimino–Brescia arteriovenous fistula, which permits repeated needling for arterialized venous blood. Many workers reported finding this method preferable to the arteriovenous shunt, and it had proved particularly helpful before transplantation, when freedom from local infection is all-important. Blood flow through the dialyser averaged over 200 ml./minute with a pump, and haemodynamic effects at other times had usually not been found to be serious.

Technique of Dialysis

A policy of increasing protein intake to 50–80 g. per day while extending dialysis time to 30–40 hours per week in three or four sessions met with general approval. The burden on patients of these long dialysing times should be diminished soon by the availability of more efficient dialysers. L. **GRIMSRUD** (Seattle) reported successful clinical trials with his foam support dialyser, which should cut dialysis time by about a third.

L. W. **FLEMING** (Dundee) showed that hypermagnesaemia develops when patients are dialysed against fluid with a "physiological" level of magnesium, though normal plasma levels can be restored if magnesium is withheld from the bath water. With his colleagues he had found a concomitant improvement in nerve conduction time, but M. **KAYE** (Montreal) thought that hypermagnesaemia protected against clinical neuropathy as well as preventing metastatic calcification.

H. G. **SIEBERTH** (Cologne) showed that twice-weekly dialysis did not completely correct the acid–base abnormalities of the patient with chronic uraemia, but left him with a permanent dysequilibrium between blood and cerebrospinal-fluid bicarbonate causing inadequate respiratory compensation for acidosis. One of the complications of correcting acidosis is that for pharmaceutical convenience dialysis solutions usually contain acetate or lactate in place of bicarbonate. H. A. Lee (Manchester) had found that this sometimes led to a rise in plasma lactate during peritoneal dialysis and thought that this might account for some unexplained convulsions during or after dialysis.

M. E. Rubini (Los Angeles) found that the daily rise in plasma urea and creatinine after regular dialysis decreased on successive days in a manner not wholly explained by redistribution between compartments. A. Scholz (Berlin) and N. Deane (New York) using carbon-14 labelled urea showed that the main factor in the case of urea is probably a reduction in extrarenal removal that accompanies the fall in plasma urea.

Transplantation

The value of integrating regular dialysis and transplantation was demonstrated by J. Vantelon from the results of the Necker unit in Paris. He could not, however, confirm previous claims that prolonged dialysis improved the chance of graft tolerance. W. Drukker (Amsterdam) showed that half of the patients receiving a graft in Europe had to wait for over four months on dialysis before reaching the head of the queue—and pointed out, moreover, that the delay was getting longer. A high standard of dialysis was required to keep the patient fit for a major operation over this period, and at present there was an appreciable mortality in the waiting period. J. Traeger (Lyons) suggested how to shorten the queue by selecting the most favourable patients. If all potential recipients were studied by ABO and leucocyte grouping a little less than half were shown to have a reasonable chance of a suitable match from a random cadaver donor or could expect to find a compatible matched donor within a few months. The remainder had a poorer chance, or had to wait longer for a suitable graft, and should be selected for long-term home haemodialysis.

The success of such a scheme depends on the predictive accuracy of leucocyte grouping. J. Dausset (Paris) reported a highly significant correlation between compatibility in leucocyte groups and long-term survival of grafts. Nevertheless, a few rejections had occurred despite perfect matching of known antigens, and hence some tissue groups had yet to be identified. S. D. Nelson (Belfast) reported no correlation between the results of the mixed lymphocyte culture test and the outcome of transplants at Boston. The normal lymphocyte transfer test did show some correlation, but since the results of this took between two and three days to obtain its use in cadaver grafting was limited—and the technique also carried a risk of transmitting hepatitis.

Even with no selection except by ABO blood-grouping, the results of cadaver grafting are improving. In the collected European series F. M. Parsons (Leeds) reported that 89 of 164 were still functioning after a median time of six months. The results from the world transplant registry, discussed by J. Crosnier (Paris), were even more encouraging. V. C. Marshall described series from Melbourne with 20 survivors out of 24 patients who had received grafts within the last 30 months. Still more impressive results with live related donors were reported by T. E. Starzl (Denver), who had a 95% survival at almost one year in patients receiving antilymphocyte globulin in addition to conventional immunosuppressive therapy.

Apart from antilymphocyte globulin there have been no technical breakthroughs to account for these steadily improving results, which must be attributed to more adequate preparation by dialysis, better surgery, and growing experience in aftercare. The value of local therapy to the graft or its lymph drainage area, suggested by the transplant registry results, received further support from studies by S. Kountz (Stanford) and A. Kirpatovsky (Moscow). Moreover, the early diagnosis of rejection is finding more secure foundation; S. Kountz had found that in most crises a fall in estimated renal plasma flow preceded all other signs of rejection, while E. S. Spencer (Aarhus) showed the value of quantitative estimation of urinary lymphocyte excretion.

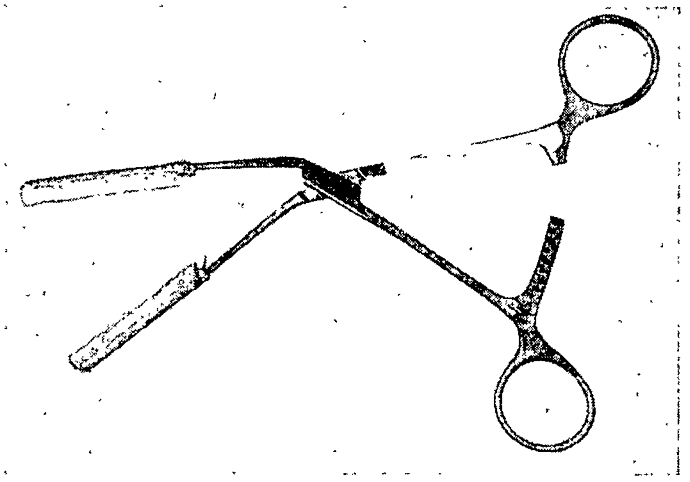
Kidney Preservation

The advent of the kidney bank still seems a long way off, but some progress with the dimethyl sulphoxide freezing technique was reported by P. B. Clark (Leeds), and the development of biochemical tests to predict viability by J. B. Dossetor (Montreal) should speed progress. Shorter term preservation of 24–28 hours is now being achieved by several workers, including J. R. Ackerman (London) and W. F. Hendry (Glasgow), using various combinations of hypothermia, hyperbaric oxygen, low-flow perfusion, and metabolic inhibition. By permitting planned daytime operations and the leisurely collection of waiting recipients on outpatient dialysis, this should be a major stimulus to the development of the dialysis–transplant unit.

NEW APPLIANCES

Modified Brown Clamp for Atraumatic Vascular Occlusion

Professor R. Y. Calne, of Cambridge, writes: In 1961 Brown described a vascular clamp utilizing sponge rubber in an attempt to duplicate the atraumatic effect of controlling a vessel between the index finger and thumb. The rubber was tied to the blades of the clamp with ligatures.



I saw this clamp being used by Dr. T. E. Starzl in Denver during renal transplantation, and have had a slightly modified Brown clamp (see illustration) in use for the past three years. I have found it extremely valuable in controlling delicate vessels. It is particularly well suited for clamping the external iliac vein during anastomosis of the renal vein in kidney transplantation.

It is atraumatic and light, being approximately the same weight as a Babcock clamp, and has a wide ratchet. The sponge-rubber pads are glued to tubular bootlace cloth with Evo-stik, and the cloth is slid over the metal blades and held in place with thread ligatures which do not distort the rubber.

The instrument was made for me by Messrs. Heaton Grogan & Co., Ltd., of 21 Bowling Green Lane, Clerkenwell, London E.C.1, and may be obtained from surgical instrument suppliers.

The "Pill" and Deep Venous Thrombosis

SIR,—A preliminary report was published by the M.R.C. Subcommittee for the study of the relations between oral contraceptives and thrombo-embolic disease (6 May, p. 335). It is striking that in this communication no statement is given regarding the criteria for the diagnosis of deep venous thrombosis. In our and others' experience the clinical diagnosis of venous thrombosis is extremely difficult and unreliable.

In a series of 512 cases, in which the diagnosis of deep venous thrombosis had been made by experienced surgeons, subsequent phlebography revealed a completely normal venous system of the lower extremity in 233 cases—that is, in 46%. Our experience from phlebographic examination performed in the acute stage of disorders of the leg with classical signs of deep venous thrombosis also showed faulty diagnosis in about 50% of the cases. From these results we concluded that a scientifically tenable diagnosis of deep venous thrombosis cannot be made without the proof of phlebography in every single case. It is hardly probable that diagnoses made by 29 practitioners are more accurate than those made by surgeons with profound experience of thrombo-embolic disease. With these observations in mind the otherwise admirable work by the committee certainly must be interpreted most critically.

Also in previously published reports of cases of venous thrombosis in women having taken oral contraceptives the final proof of correct diagnosis by phlebography is lacking but for a few exceptional cases. Moreover, studies of the coagulation pattern in patients taking oral contraceptives failed to reveal any basis for the assumption that these drugs might induce thromboembolic disease.—We are, etc.,

Overinflation of the Lungs of Coal Miners

SIR,—In their article "Overinflation of the Lungs in Coal Miners" (1 July, p. 10), Dr. Colin Ogilvie and others suggest that the pulmonary function in a group of miners with unexplained dyspnoea is "compatible with some of the reported pathological features of focal emphysema, due to coal dust." This conclusion is open to an alternative interpretation.

The miners they studied (Group 1) were selected on the basis of excessive dyspnoea alone, and may, therefore, not form a homogeneous group with respect to its aetiology. If this is the case, conclusions drawn from the mean results are likely to be misleading. Analysis of the authors' data reveals that the lung function of the five miners with "signs of bronchitis" but no radiological pneumoconiosis resembles that of other men with bronchitis uncomplicated by emphysema.[1] The six miners with radiological simple pneumoconiosis but no "signs of bronchitis" have, on average, less impairment of function. This is a likely consequence of both the factors which lead men to apply for compensation[2] and the known features of the condition.[3]

	V.C. (l.)	F.R.C. (l.)	R.V. (l.)	T.L.C. (l.)	M.V.V. (l./min.)
A	2·18	5·54	4·88	7·06	39·2
B	2·92	3·90	3·18	6·12	75·0
C	4·1	3·9	2·1	6·3	—

Mean values
A—5 men having "signs of bronchitis" without pneumoconiosis.
B—6 men having pneumoconiosis without "signs of bronchitis."
C—Average values for normal men having the ages and heights of Group B[4].

The findings in these two sub-groups of Ogilvie's cases are summarized in the Table, together with average normal values for the second group, which we believe to be more appropriate than those quoted by the authors. The values for the remaining six coal miners who have both pneumoconiosis and signs of bronchitis (two subjects) or neither of these conditions (four subjects) lie mostly within the limits of the other two groups.

Inspection of the Table suggests that the abnormal residual volumes (R.V.) and vital capacities (V.C.) in the coal miners with pneumoconiosis but no "signs of bronchitis" are due to the remarkably low expiratory reserve volumes—that is, F.R.C.-R.V. This result may be due to mild chronic bronchitis, not accompanied by physical signs, but in view of the normal functional residual capacities (F.R.C.) failure to expire fully from F.R.C. to R.V. is an alternative explanation; this should not be overlooked in patients with a possible "compensation neurosis."

We do not rule out that radiological signs of pneumoconiosis may be obscured by focal emphysema. However, this is unlikely in view of the recent finding that the degree of focal emphysema is positively correlated with both *x*-ray category of simple pneumoconiosis and the content of coal dust in the lungs at postmortem.[5]

In summary, it seems that the "unexplained dyspnoea" of the miners in this series may be explained in most instances by impairment of function due to chronic non-specific lung disease, while in the remainder psychological factors may contribute to the symptoms. No good case appears to have been made for co-existence of focal emphysema, the detection of which during life is likely to require application of the refined methods for analysing lung-gas distribution now available.—We are, etc.,

SIR,—The article in your issue (1 July, p. 10) by Dr. C. Ogilvie, Dr. K. Brown, and Dr. W. E. Kearn is a most valuable contribution. Industrial physicians and radiologists have long been aware of the fact that some workers occupationally exposed to inhalation of non-silicious dusts, of coal in particular, may suffer from severe disabling symptoms of pulmonary insufficiency without clinical (radiographic) evidence of pneumoconiosis. Now for the first time Dr. Ogilvie and his colleagues have documented this in a fair number of coal miners with exact pulmonary function studies.

In their discussion the authors concentrate attention on explaining both the latency of dust lesions in the radiograms as well as the presence of pulmonary insufficiency by the same factor, namely overinflation—that is, emphysema in the lungs. Referring to my letter to the editor on the same subject (28 May, 1966, p. 1356), they mention the possibility I suggested of emphysema attenuating the shadows cast in radiograms by dust in the lungs. Regarding the origins of overinflation and emphysema, the authors resort to the theory that the dust lesions are of a particular kind and distribution which produces a special type of so-called "focal emphysema."

Of course the authors have no proof of attenuation of shadows of dust lesions in their radiograms in the over-inflated lungs of these coal miners. Nor do they have proof for the assumption that the severe pulmonary insufficiency symptoms were caused by the overinflation emphysema which they describe. What they did demonstrate, however, is the fact that in coal miners long exposed to inhalation of coal dust symptoms of severe pulmonary insufficiency may be present even in the absence of radiographic evidence of dust lesions in the lungs. This fact presents a problem which is not solved by assumptions regarding the nature of overinflation (emphysema) and its shadow-attenuating effect on the radiograms. The problem only gets lost in the vast complexities of the larger problem of emphysema, which still remains unsolved even after the stupendous amount of research, study, and discussions in dozens of symposia recently held here and abroad. In the present state of hopeless confusion about this subject emphysema and pulmonary insufficiency are considered synchronous events and even conterminous conditions. In fact, there seems to be now little awareness of what the real problem is regarding the nature and origin of pulmonary insufficiency resulting from long exposure to inhalation of dust which fails to be removed from the vast internal surface of the ultimate structures of the lungs.

My comments are concerned mainly with this problem. I proposed a new concept of the "visceral function of the lungs." I described this in a series of publications over the past three decades.[1-3] In my theory this vital function consists in activities by which the alveolar structures constantly recreate the vast and most delicate yet completely mobile internal surface membrane, adapting it constantly to the momentary requirements of the function of the lungs as a whole. Although this new concept is still largely theoretical, it can be said that it has already gained abundant substantiation in the recently evolved new chapter of pulmonary physiology. This has revealed the vital role of the highly active alveolar membrane, which constantly secretes and constantly spreads a new surfactant semifluid film over the vast internal lung surface. In this new concept overinflation and emphysema are interpreted as merely incidental phenomena of dysfunction of the lung's ultimate structures in response to loss of internal lung surface, which can be caused by a great variety of factors, including encumbrances of the delicate lung surface by dust which fails to be removed (failure of self-cleansing) owing to dysfunction of affected structures.

Considering the rapid progress made in this new field of pulmonary physiology[4-6] we may now look forward with confidence to the time when our knowledge about the functions of the alveolar structures and the vast internal surface membrane will enable us to make reasonable assumptions about the nature and origin of pulmonary insufficiency caused by excessive deposits of dust on the internal lung surface interfering with its functions, even though the presence of the dust cannot be demonstrated in radiograms.—I am, etc.,

Tests for Lead Poisoning

SIR,—In the report of the investigation of lead poisoning in Bradford (1 July, p. 56) in which seven children and two adults were investigated in hospital, and two of the children died, no mention is made of blood lead, nor urinary lead, nor urinary coproporphyrin, nor urinary δ-aminolaevulinic acid. This is surprising, as these are the four best tests for lead exposure and lead poisoning.[1]

Blood lead and urinary lead are specialist analyses. The Occupational Hygiene Service attached to the Nuffield Department of Occupational Health, Clinical Sciences Building, York Place, Manchester 13, does some 5,000 such estimations annually for hospitals and industry. The service provides the special heparinized syringes for taking the blood samples and the deleaded urinary containers required; the samples are returned by post.

This excellent service should be used to the full by all responsible for the investigation of children and adults where a diagnosis of lead poisoning is remotely possible, and for the control of lead absorption in industry. Since the reliability of the result and the cost of analysis are related to the number of samples analysed, it is normally desirable to use one specialist laboratory.—I am, etc.,

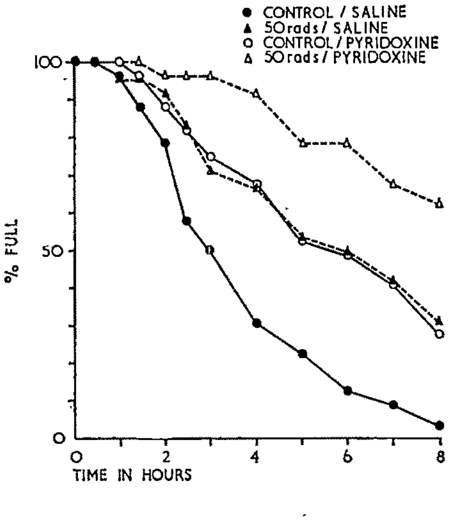
Treatment of Radiation Sickness

SIR,—As the investigation of the usefulness of pyridoxine hydrochloride in radiation sickness by Dr. H. Mattie and others (22 July, p. 215) does not provide a conclusive answer, the following unpublished experiment, performed some years ago, may be of interest.

Rats cannot vomit, but relatively low doses of radiation produce a delay in gastric emptying. The phenomenon can be investigated by allowing rats to feed themselves with a thick paste of a commercial barium meal preparation before irradiation and then following the emptying of the stomach by means of serial radiographs.[1] The technique can be readily adapted to study the effects of radioprotectors and sensitizers[2] and pyridoxine has been tested in this way. Six litters of four adult albino rats were used. After feeding a standard quantity of barium meal two rats of each litter were injected intraperitoneally with 50 mg. of pyridoxine hydrochloride in 1 ml. of saline and the other two were given a similar injection of 1 ml. of physiological saline. Immediately following the injections one of the two rats given pyridoxine and one of the rats given saline were irradiated with 50 rads of *x* rays. The other two rats were mock-irradiated so that separate comparisons could be made of the effects of the radiation and the pyridoxine.



The accompanying graph illustrates the rate at which the stomach emptied during the eight hours after irradiation. Pyridoxine by itself, in the dosage used, delayed gastric emptying as much as 50 rads of *x* rays, and when the two were combined the gastric delay was greater than with either alone. Thus pyridoxine did not counteract the effects of radiation on gastric movement in the rat.

Radiation-induced delay in gastric emptying is presumably an unpleasant experience for the rats, as they subsequently develop an aversion to the barium meal eaten immediately prior to the irradiation.[3] It seems reasonable to assume that the gastric delay is the counterpart of radiation-induced nausea and vomiting in man. If so, this experiment suggests that pyridoxine is not likely to counteract this particular effect of radiation. Pyridoxine may have actions on other symptoms of radiation sickness, but if so these have still to be proved.—I am, etc.,

Carcinogenic Properties of Ortho-dianisidine

SIR,—The letter on carcinogenic properties of ortho-dianisidine (22 July, p. 238) and your leading article on carcinogenic hazards (same issue, p. 189) draw attention to the possible risks in using ortho-dianisidine and also ortho-tolidine in the clinical routine laboratory.

Unfortunately, we are not given firm advice. Should we discontinue the use of these reagents? In this laboratory, for example, we are using ortho-tolidine for the testing for occult blood in stools, and for estimating blood sugar in the automatic analyser and also in emergencies by a hand method. This amounts to 9,385 estimations a year. The advantage of the ortho-tolidine method for estimating blood sugar is that one measures the true glucose and no other reducing substances. To give up these techniques means going back to the times when one estimated overall reducing substances.

Is it safe to continue with techniques employing ortho-tolidine—naturally with precautions such as using automatic pipettes—when this substance is dispensed?—I am, etc.,

Trismus Following Inferior Dental Nerve Block

SIR,—It would be interesting to know if the condition described by Drs. H. C. Killey and L. W. Kay (15 July, p. 173) really is occurring more frequently, or are more patients reaching them because of their efficacious treatment? Certainly in the case of a patient I saw some years ago I felt that the length of treatment could be a factor, since his dentist had worked for over two hours. Longer treatment times are nowadays quite common with premedication and sedation techniques preceding local or regional anaesthesia.

Having recently studied 10 routine dissections and carried out two special dissections, I am very aware that both large and small vessels are readily available for puncture where a needle may be inserted to block the inferior dental nerve. In consequence, I shall never give another inferior dental block injection without an aspirating syringe.

It seems difficult to believe that this progressive trismus in three or four days can be due to "organization of a band of fibrous tissue"—maybe it is hydrostasis, and aspiration under general anaesthesia in one of their patients might be very interesting.

Several authors have described this complication,[1-3] but the most fascinating article is that by John Campbell.[4] This is a careful account and discussion by an astute dentist of his own affliction: "At the end of the sixth week the first signs of remission came. . . . I reacted philosophically to the incident." Little wonder that Killey and Kay get so many of these cases—even John Campbell might have taken "the dreary road to the south."—I am, etc.,

Investigating Hypertension

SIR,—May we comment on the letter (29 July, p. 306) in which Wing Commander P. W. Robertson refers to our paper on aortography in the investigation of hypertension ?[1]

We remain quite unashamed that we should attempt to assess the chances of ultimate benefit to the individual when deciding whether or not to perform an investigation on a patient. Far from being a "novel approach" or a "curious parameter" we regard this as an essential of ethical practice.

It is a truism that accurate diagnosis should precede treatment, but clinical medicine is full of situations where to pursue diagnosis to its ultimate detail, though intellectually satisfying, may expose the patient to some risk without altering the correct treatment in the least. In any case, before adopting an attitude of academic superiority it is important to ensure that the investigation advocated is capable of supplying the required answer. In these particular circumstances the relevant questions are:

(1) Has this patient a vascular lesion conceivably the cause of the hypertension ?

(2) Is that lesion in fact the cause of the hypertension or the result of it or merely coincidental ?

(3) Will appropriate surgical treatment of that lesion result in relief of the hypertension ?

Aortography is inherently incapable of answering more than the first question, and without a reliable means of obtaining answers to the others' aortographic findings are of very limited value. The coexistence of a narrow renal artery and hypertension has become a classical chicken-and-egg dilemma. Unfortunately, the various attempts to solve the dilemma such as divided renal function studies, angiotensin infusion, and estimations of blood levels of renin or angiotensin have not proved reliable, and surgery must be advocated or withheld on largely empirical grounds. In these circumstances, and considering the availability and efficiency of drug treatment, we cannot think it proper to subject every hypertensive requiring treatment to aortography as Dr. Robertson appears to advocate. In Dr. Robertson's recent paper,[2] to which he refers, there is no attempt at proof of an aetiological relationship between the vascular abnormalities demonstrated and the coexisting hypertension of the patients studied.

The manifest differences between bronchial carcinoma and surgically correctable hypertension, particularly in terms of relative frequency, morbidity of the appropriate investigations, and the availability and likelihood of success of non-surgical treatment, make Dr. Robertson's analogy between investigating the two conditions peculiarly inappropriate.

Dr. Robertson chides us for drawing conclusions from a highly selected series. We reported on every patient who had undergone aortography for the investigation of hypertension at a London teaching hospital. The series which Dr. Robertson quoted in his support[3] had a male-to-female ratio of nine to one, and two-thirds of the patients were Service personnel.

We would not wish to advocate diagnostic nihilism but merely recognition of the limitations and potential dangers of a particularly diagnostic technique. Our aim was and is to warn against the uncritical submission of large numbers of patients to aortography in the hope that this will provide a diagnostic answer that it is incapable of doing.—We are, etc.,

Elusive Popliteal Pulse

SIR,—As one familiar with vascular surgery from the beginning I was interested to read your leading article (5 August, p. 326) suggesting that the best way of feeling for the popliteal pulse is to have the patient in the prone position. With this I agree, but think that further advantage is to be gained by passively flexing the knee-joint. You mentioned this for the supine position but not for the prone.

In extension the tissues of the popliteal fossa are tense, whereas in passive flexion they are relaxed and the artery is then more easily palpable. At the same time the palpating index or middle finger of one hand, if placed over the artery and pressed down by the index or middle finger of the other hand, is more sensitive to pulsations than if pressed down by muscle action of its own side. This means that it is best for the leg to be held in flexion by an assistant, but it can be maintained in that position by supporting the foot and ankle against the examiner's shoulder.

Yet another reliable observation is to watch from the side the foot of the uppermost leg when the patient sits with his knees crossed ; it has to be a severely impaired pulse before oscillation is completely eliminated. This, admittedly, is qualitative rather than quantitative.—I am, etc.,

F. A. R. STAMMERS.

Birmingham Regional
Hospital Board,
Birmingham 16.

SIR,—With reference to your leading article (5 August, p. 326) may I suggest a visual method ?

The subject sits in a chair, crosses one knee over the other with the popliteal space being examined applied to the opposite patella. He then relaxes, thus compressing the popliteal artery by the weight of the leg.

Distinct movements of the foot, synchronous with the pulse, can be seen (like miniature knee jerks) if the popliteal artery is pulsating.—I am, etc.,

West Runton,
Norfolk.

LUCY TURNER.

SIR,—I have found the following technique most satisfactory in enabling the students to display to themselves pulsation of the popliteal artery or its absence. The supine patient's knee is supported slightly flexed by one hand in the popliteal fossa. The other hand presses the patella downwards and backwards, causing some reflex contraction of quadriceps and relaxation of the antagonistic hamstrings. The pulse, if present, is always palpable in this way.—I am, etc.,

AUSTIN T. CARTY.

Mater Misericordiae Hospital,
Dublin 7.

Chemical Treatment of Skin Cancer

SIR,—I was rather concerned to read in your leading article "Chemical Treatment of Skin Cancer" (15 July, p. 125) that "5-fluorouracil . . . is not suitable for the treatment of basal cell carcinomas, let alone squamous carcinomas." This statement gives a misleading impression, since Dr. E. Klein and his co-workers in the paper you quoted[1] made this statement in connexion with the routine clinical management of solitary basal cell carcinoma. They go on to state that this may not be true as regards the management of neoplastic lesions in which standard therapeutic methods are complicated by the large areas of skin involved, such as multiple superficial basal cell carcinomas or extensive solar or arsenical keratoses.

During the past 12 months I have been using 5% 5-fluorouracil ointment initially in the treatment of superficial recurrences of basal cell carcinomas previously treated by irradiation, and more recently as the primary treatment of carefully selected superficial basal cell and intra-epidermal carcinomas.

It is, of course, much too early to assess the long-term success rate of such treatment, but so far the results have been quite impressive and a number of significant facts have emerged from the trial:

Proper selection of cases is essential.

Recognition of the end point of treatment is difficult and comes only with appreciable clinical experience of the technique.

Adequately treated lesions heal completely with an absolute minimum of scarring.

The apparent absence of deep scarring and endarteritis permits the safe use of superficial irradiation at a later date should there be a residue or recurrence within the treated area.

Superficial recurrences within previously irradiated areas can be treated successfully without the risk of inducing radionecrosis or additional scarring.

Prolonged application to large areas or tumours does not produce any systemic disturbance or detectable changes in the peripheral blood picture.

Treatment is virtually painless, and in my experience can be on a domiciliary basis with weekly supervision.

It may well be that topical chemotherapy has a distinct therapeutic advantage over low voltage irradiation for the treatment of spreading superficial lesions involving irregular surfaces, especially around the pinna and external ear.

It would be a great pity if at this stage the impression is gained that topical chemotherapy has nothing to offer in the treatment of any type of skin cancer. Rather should it be stated that this treatment may well have an important role in its own right as the primary treatment of certain specific types of skin tumours.—I am, etc.,

G. M. KING.

Two Types of Breast Cancer?

SIR,—For the past two decades it has been debated[1] whether the change which occurs at middle age in the rate of breast cancer mortality is evidence for two types of breast cancer. The presence of the rate change is confirmed by recent mortality data[2] (Fig. 1) for which random fluctuations were minimized by calculating mean annual mortality values for a period of years (1958–63) and for large populations (England and Wales, Denmark, Finland, and Japan). On the assumption that two distributions (I and II) of breast cancer were present, the incidence of II was estimated by extrapolating linearly, on a log-log plot, the mortality rates for older ages, which were assumed to refer essentially to II. The conjectured incidence of I was then obtained by subtraction (Fig. 2).

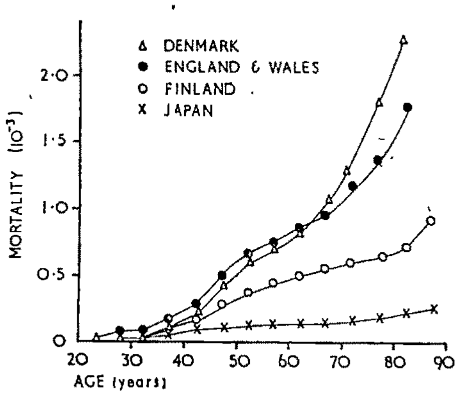

FIG. 1

From the areas under each curve (Fig. 2) I would account for approximately half of the total breast cancer mortality in England and Wales, Denmark, and Japan (data not shown). For England and Wales, the relative frequency of I and II is approximately five, in the age group 30–55 years, and unity for 55–70 years. At ages greater than 70 years, II increases steeply and is 10 times more frequent than I at 75 years, and 100 times at 80 years.

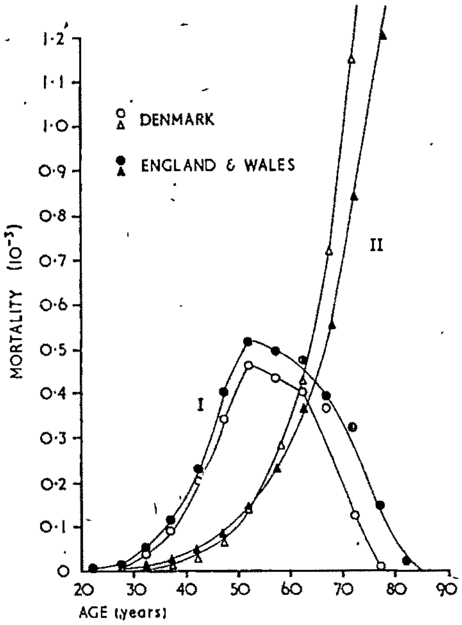

FIG. 2

It is reasonable to postulate that I would be oestrogen-dependent, while II would thrive in the absence of oestrogen. Thus, comparison of success rates of endocrine therapy for breast cancer, in the three age groups quoted above, might provide evidence in support of, or against, the existence of two biochemically distinct types of breast cancer, for which the above epidemiological evidence is highly indicative but not, by itself, conclusive.—I am, etc.,

Digital Ischaemia and Malignant Disease

SIR,—I was interested in the association of digital ischaemia and malignant disease (22 July, p. 208), but disappointed with the authors' speculations on the mechanism, and particularly the reluctance to attribute the phenomenon to intravascular coagulation.

Increased blood viscosity in the small digital arterioles, which are subject to surface cooling, must be the final mechanism and be the result of red cell and platelet aggregation together with hypercoagulability of the plasma. Crenated red cells,[1] increased platelet numbers and stickiness, raised levels of fibrinogen and of factor VIII with accelerated generation of thromboplastin,[2] are all recognized in malignancy. As evidence of intravascular coagulation raised levels of cryofibrinogen may be found,[3] and fibrin breakdown products detected. Certainly in some cases the trigger is the release of tissue thromboplastin from disseminating carcinoma cells, and tumour emboli can be shown to be associated with fibrin thrombi.[4 5] Particularly is this so with the mucinous adenocarcinomata[6]; fibrin or fibrinoid may be found in the renal glomeruli.

Intravascular coagulation is a common pathogenetic mechanism in diverse pathologies,[7 8] and our understanding of these states will only be advanced when the clinician recognizes by the high index of suspicion the type of case that requires subtle investigations.—I am, etc.,

Royal Victoria Infirmary,
Newcastle upon Tyne.

SIR,—I enjoyed reading the paper by Dr. P. R. Hawley and colleagues (22 July, p. 208). However, I should like to point out that a definition of primary Raynaud's disease was formulated by Allen and Brown in 1932,[1] on the basis of their extensive experience of this condition. They stated that a diagnosis of Raynaud's disease should be made only when the following criteria were fulfilled: attacks of pallor and numbness of the extremities, proceeding to cyanosis and redness; *absent or minimal gangrene*, onset early in life and *duration of symptoms exceeding two years*; and no obvious demonstrable cause (my italics).

This definition would appear to be still valid in the light of more recent experience of this condition.—I am, etc.,

D. N. GOLDING.

Undesirable Effects of Marijuana

SIR,—I have not seen the effects of marijuana as used in this country, but three cases of acute intoxication from smoking Indian hemp seen when a medical missionary in India come vividly to mind.

Some hospital outbuildings were under construction, leaving a series of unroofed gables. On the nine-inch wide (23-cm.) pinnacle of one of these stood a man, stark naked, shouting and singing and beating his chest by the light of the setting sun. I had to bring him down, fortunately without damage to either of us.

Two other cases might be described as "fighting drunk." A policeman at the local gaol ran amok, armed with a carbine. I was the medical officer, and was relieved to find his colleagues had overpowered and disarmed him by the time I arrived. On another occasion there was an uproar on the hospital veranda. Running out from my house to see what was the matter I was in time to see a male charge nurse felled with a blow from a powerful man. Grateful for the mosquito screening which separated us I kept the patient humoured in conversation until reinforcements arrived.

In other words, the effects of smoking Indian hemp can range from elation to manic violence.—I am, etc.,

E. GORDON WILKINS.

St. Mary's Hospital,
York.

Dopa and Parkinsonism

SIR,—My colleagues and I are thankful for the generosity displayed in your leading article (24 June, p. 783) about DL-dopa and Parkinsonism.[1] Your recognition of the necessity for continuing investigations is a service to those afflicted with this disease.

Our current studies with L-dopa strengthen the therapeutic effects listed in your article. Yet the following might be noteworthy: (1) Our initial failure to observe therapeutic effects in early, unilateral cases might well be a consequence of our reluctance to risk drug toxicity in mild cases. (2) To date, toxic manifestations have been sporadic, unpredictable, and reversible. They have included nausea, vomiting or faintness, depression of the circulating granulocytes, transitory eosinophilia, statistically significant elevation of the blood pressure, statistically significant elevation of the blood urea nitrogen, and involuntary movements, which usually affected the face, the jaw, the tongue, or the anterior neck, but occasionally the trunk or the extremities.

Parkinsonians represent as a rule the older segment of the population, and sometimes they suffer from complicating diseases as well. These patients have been often subjected to extensive drug exposure prior to receiving dopa. Inevitably, additional toxic manifestations will emerge while the action of dopa on Parkinsonism continues to be studied. Hence, we still consider our own studies as purely experimental. We are conducting them on informed patients, confined in a fully equipped metabolic ward, under systematic medical, nursing, and laboratory supervision of their health.—I am, etc.,

Guillain-Barré Syndrome with Leukaemia

SIR,—I read with interest the report by Drs. R. L. Powles and J. S. Malpas of two cases of this syndrome in patients with chronic lymphatic leukaemia (29 July, p. 286) and note that one of them (Case 2) had also suffered herpes zoster 10 months previously.

In 1963 I admitted a known chronic lymphatic leukaemia patient to Bristol Royal Infirmary with a clinical diagnosis of acute polyneuritis occurring five days after an attack of zoster. After investigation this was confirmed and the case was subsequently reported by Drs. Etuk and Bridges.[1] These writers referred to three cases of polyneuritis complicating herpes zoster reported by Knox *et al.*[2]—the latter also reviewing 10 further cases from the literature. Whereas in my patient the latent period between the zoster and the polyneuritis had been only five days, Knox reported a range in the 13 cases of a few days to two months.

While "activation" of the varicella-zoster virus is a well-recognized hazard in patients with reticuloses (indeed sometimes characteristically to the extent of a generalized zoster) the added complication of polyneuritis even in these circumstances appears to be rare. None of Knox's 13 cases had any evidence, at the time, of reticulosis.

Although the 10 months which Drs. Powles and Malpas give as the latent period in their Case 2 would appear to be well outside Knox's range, is it not worth considering the possibility that the polyneuritis in this case may have been related more to the preceding zoster than to the pre-existing leukaemia?—I am, etc.,

Changed Character of Osteomyelitis

SIR,—Your leading article on the "Changed Character of Osteomyelitis" (29 July, p. 255) comments on many interesting aspects of this disease. But in children and adolescents, is not the usual site of disease the metaphysis and not the epiphysis?

I would also question the statement that the blood culture is usually negative even in subacute cases of the disease and the presence of a sequestrum is surely a common cause of a persistent sinus.

The importance of instituting antibiotic therapy as soon as the diagnosis is made is rightly stressed. Broad spectrum antibiotics are recommended but not named. Tetracycline and chloramphenicol are not ideal, as they are not bactericidal drugs, and ampicillin does not act against the penicillin-resistant *Staphylococcus aureus* which is now so commonly found in cases of osteomyelitis. As penicillin-sensitive and penicillin-resistant staphylococci cause the great majority of bone infections, the initial antibiotic therapy should be planned accordingly. Cloxacillin may be given alone[1] or combined with penicillin, fusidic acid, cephaloridine. lincomycin, or ampicillin. If pus forms under the periosteum, as it often does, it can be effectively removed by aspiration with less risk of secondary infection than if an incision is made.[2] If incision is favoured, suturing the wound lightly rather than accurately is likely to increase the risk of secondary infection and subsequent sinus formation.—I am, etc.,

J. H. BULMER.

The Royal Hospital,
Wolverhampton.

REFERENCES

[1] Green, J. H., *Brit. med. J.*, 1967, 2, 414.
[2] Neligan, G. A., and Elderkin, F. M., ibid., 1965, 1, 1349.

SIR,—While I agreed with much of your leading article on "Changed Character of Osteomyelitis" (29 July, p. 255) it contains in my view too many inaccuracies to pass unchallenged.

Surely the epiphysis is very rarely affected, even secondarily? The usual site is the metaphysis.

If the lesion needs surgical exploration, drilling the underlying bone is always wise; pus is quite often found under tension within the bone, even when a subperiosteal abscess is present. No harm results even if intraosseous pus be not found. Primary osteomyelitis in the adult, although admittedly uncommon, is by no means "extremely rare" in my experience.—I am, etc.,

Cambridge. T. J. FAIRBANK.

SIR,—Your leading article on the changed character of osteomyelitis (29 July, p. 255) suggests that the disease has lost its sting all over the world. This is certainly not the case in West Africa, where chronic osteomyelitis is one of the major orthopaedic problems. Both massive sequestration and diffuse infection leading to an enlarged sclerotic bone riddled with abscess cavities are commonplace.

In Nigeria the causative organism is usually, except in sicklers, a penicillin-sensitive strain of *Staphylococcus pyogenes*.

The majority of patients get no proper treatment in the acute stage. This may be due to lack of medical facilities, but often follows mistaken diagnosis. The child is brought to hospital with a painful swollen limb following a fall. If the doctor does not think of osteomyelitis he may examine the limb to exclude a fracture and discharge the patient, thereby losing the chance of curing the condition by the early administration of antibiotics.—I am, etc.,

D. R. RICHARD.

Department of Surgery,
University of Ibadan,
Nigeria.

Recognition of Heart Failure

SIR,—The article "Recognition of Heart Failure" (22 July, p. 219) is lucid and valuable, but there are two statements which I think are misleading.

Dr. C. S. McKendrick claims that "it is rarely necessary to differentiate which sort of triple rhythm is present." But an atrial sound is not in itself evidence of heart failure, though it does imply resistance to filling of a ventricle, and therefore abnormality. An atrial sound may be present intermittently, and for a long time, before left ventricular failure develops in patients with ischaemic heart disease, aortic stenosis, or hypertension. A third sound, on the other hand, is evidence of failure and of raised left atrial pressure in patients over 40 and without mitral regurgitation. These sounds, therefore, have very different implications and it is worth while trying to separate them. I agree that when tachycardia is present this may be impossible.

Secondly, it is claimed that the central venous pressure does not rise after myocardial infarction, but this is certainly not true. A raised jugular venous pressure is frequent following myocardial infarction when left ventricular failure is present. It is presumably due to consequent pulmonary arterial hypertension and right ventricular failure, and this may occur rapidly and therefore be seen when the patient still has pain. Elevation of the jugular venous pressure is therefore not a distinguishing point between pulmonary embolism and myocardial infarction, unless left ventricular failure can be confidently excluded.—I am, etc.,

PETER CARSON.

Cardiac Arrest in Asthma

SIR,—A great deal of interest has been shown recently in sudden death during status asthmaticus (25 March, p. 756, and 22 April, p. 244), and so we feel that the following case with two episodes of cardiac arrest following withdrawal of steroids may be worthy of description.

The patient, an asthmatic aged 47 years, who had been maintained on betamethasone 0.25–0.5 mg. daily for three years, was admitted on 2 December 1966 with a five-day history of melaena. Aspirin had been ingested, and he had a haematemesis on the day of admission. When seen in hospital he was pale and sweating, with a regular pulse (104/min.) and blood pressure of 150/85 mm. Hg. Hb 47% (6.9 g./100 ml.). Bronchospasm was minimal. 5 pints (2.8 l.) of blood was given. Barium meal examination showed a duodenal ulcer and steroids were withdrawn. In spite of tetracycline and long-acting isoprenaline he developed purulent sputum and increasing bronchospasm, failing eventually to respond to intravenous aminophylline. During a period of 17 days there were no signs of adrenal insufficiency.

On 19 December 1966 he was in severe bronchospasm and using his isoprenaline inhaler to excess, with less than a minute between five successive inhalations. At 10 a.m. cardiac arrest occurred in asystole. External cardiac compression was begun immediately with return of sinus rhythm within five minutes. Several ribs were broken during compression. Intubation was performed for assisted respiration with 100% oxygen. After 10 minutes spontaneous breathing started. Arterial blood gases showed metabolic and respiratory acidosis. The former was corrected by intravenous 8.4% sodium bicarbonate. Hydrocortisone was administered intravenously, and thereafter oral prednisolone. By 11 a.m. he was fully conscious. The E.C.G., continuously monitored, showed the development of right bundle branch block.

At 3 p.m. on the same day further cardiac arrest occurred in asystole. Further successful resuscitation followed, and on this occasion sinus rhythm returned spontaneously without bundle branch block. Flailing of the left chest was noted, and intermittent positive pressure ventilation was started in the intensive care unit. Severe bronchospasm persisted despite hydrocortisone and intravenous aminophylline, and indeed the Barnet ventilator was failing to inflate the chest despite a pressure of 45 cm. of water. A prophylactic left intercostal drain was inserted and bronchopleural leak became apparent. Tubocurarine 15 mg. and promazine 50 mg. were given at regular intervals, with 100 mg. ampicillin four-hourly, all by transvenous infusion. Repeated doses of dilute adrenaline were given intravenously to lessen the bronchospasm. Tracheostomy was performed the following day. Blood pressure remained satisfactory.

Assisted respiration was continued until 23 December 1966, when blood gas figures were satisfactory and adrenaline was no longer required. Uninterrupted clinical progress followed, and the prednisolone was reduced to a maintenance dose of 5 mg. b.d. At follow-up four months later bronchospasm was minimal.

In this case an isoprenaline inhaler was used over-enthusiastically during a severe asthmatic paroxysm, with resultant excessive sympathomimetic effect. This has been noted recently to be a likely mechanism of cardiac arrest in such patients.[1 2] The combination of status asthmaticus with flail chest is a desperate situation even with modern methods of respiratory assistance.[3] Our patient had bronchospasm of sufficient severity to resist artificial ventilation. The use of adrenaline intravenously is not without risk in itself, and continuous E.C.G. monitoring in such a situation would seem all important.—We are, etc.,

Pressurized Aerosols in Asthma

SIR,—I would like to add to the observations recently published in the *B.M.J.* concerning pressurized aerosols in asthma (13 May, p. 441, and 10 June, p. 699). It may not be generally appreciated that a drug administered into the tracheobronchial tree is absorbed very rapidly. In fact Redding *et al.*[1] have shown that dilute solutions of adrenaline in water administered by this route are as rapidly effective as intravenous or intracardiac injections.

This fact should be borne in mind when tracheobronchial aerosol administration of any drug is contemplated, and particularly so with powerful agents such as adrenaline and isoprenaline.—I am, etc.,

Stress Incontinence Treated by Electrical Stimulation

SIR,—Mr. Thomas Moore and Mr. P. F. Schofield (15 July, p. 150) point out that maximum perineal electrical stimulation can have a curative effect on stress incontinence. I have made the same chance observation on patients with stress and urge incontinence when stimulating their pelvic floor muscles during investigations of the electrical potentials of the levator ani under light anaesthesia. Although several hundred patients have had endoscopy and other manipulations under anaesthetic spectacular improvement in the condition has been confined to certain of those patients whose pelvic floor muscles were strongly stimulated, either during the procedure or later by electrodes temporarily inserted in the pelvic floor muscles during the anaesthetic, as a means of assessing the possible value of implanted electronic devices at a later date.

It has not been possible to predict the effect of strong stimulation in any given patient, but the results, in the main, accord with those of Moore and Schofield in that they are mainly confined to stress incontinence and "urge-frequency." However, one male adult patient with an incomplete cauda equina lesion due to spinal injury three years earlier has shown a remarkable improvement in that his constant dribbling has been replaced by pure stress incontinence and a number of children of both sexes with enuresis and diurnal urge-frequency have been relieved of their diurnal symptoms following strong stimulation during light anaesthesia.

My methods are rather similar to those of the authors in that, using a square wave of 1–2 milliseconds' duration and pulse frequency of 30 per second, I increase the voltage until the anus is seen to contract and then to be pulled forward and upward, indicating that there is a strong contraction of all the pelvic floor muscles.

This observation tends to confirm the view I have expressed[1 2] that the basic cause of many cases of stress and urge incontinence is "weak pelvic floor syndrome," but it is not as yet by any means fully explained.—I am, etc.,

Enuresis and Psychiatry

SIR,—I am rather surprised by some of the statements that have been made in the correspondence (15 July, p. 176, and 29 July, p. 308) on the above subject. In particular, I know of no evidence that treatment of enuresis with the buzzer may give rise to impotence later in life. Moreover, there is now quite an extensive literature supporting the effectiveness of conditioning treatment using the "pad and buzzer," the value of which has been pointed out in your columns, for example, by Gairdner.[1]

In this department we make regular use of the buzzer and hold a stock of about a dozen machines which are lent out to patients. There are, however, certain points which may be worth making about the treatment.

(1) We see a small minority of patients in whom the enuresis is part of a more general emotional disorder. In such cases it is usual to find that the child has become dry at night as a toddler and that with the subsequent development of anxiety symptoms of various sorts enuresis has also appeared. It is not our practice initially to treat such children with the buzzer but to apply whatever means of psychiatric treatment appear appropriate to the problem as a whole. Often the enuresis subsides when these measures are successful, but, if not, conditioning can then be employed.

(2) About 90% of the enuretics we see do not fall into the above category and in the majority of these (about four out of five) there is a prompt and satisfactory response to conditioning therapy. However, the relapse rate is quite high, in the vicinity of 50%, though relapse almost invariably responds promptly to a further short course of treatment; occasionally two or three further courses of treatment are required, but the later ones usually need to be only very brief.

(3) Most of these children suitable for treatment with the buzzer have had lifelong enuresis and there may be emotional symptoms secondary to the enuresis. These are consequent upon the disapproval which it has brought from members of the family and others, and the child may feel guilty, anxious, or even depressed. In these cases there is often a marked improvement in the child's emotional state following successful treatment of the enuresis.

(4) In using the buzzer it is important to gain the active and willing co-operation of both child and parents before treatment is commenced. Some children, particularly younger ones, are initially frightened of the apparatus, and the treatment has to be carefully explained and discussed with them, sometimes over the course of two or three interviews. Provided this is done it is often possible to treat successfully children as young as age 6 or even a little younger. I have also found it useful to arrange to see the patients quite frequently while they are undergoing treatment in order to ensure that the apparatus is being used properly and to give support and encouragement in its continued use.

I agree with Dr. I. G. Wickes (15 July, p. 176) that substitution symptoms rarely occur ; in fact the disappearance of other symptoms is more common. Occasionally, however, a persisting psychiatric problem is found to exist when the enuresis has ceased, and, if so, this has to be treated on its own merits. In my view it is wrong to regard enuresis as necessarily and invariably a symptom of a more deep-seated emotional disorder ; while it is sometimes this, I think it is much more often a " developmental " phenomenon, as described by Barbour and his colleagues.[2] Nevertheless, it must be admitted that there is a minority of children (about 20%) who, though apparently suitable for conditioning therapy, do not respond. They are usually in their teens, and one wonders if they would have done better treated younger. They present a very difficult treatment problem and are perhaps those which end up in Dr. R. A. B. Rorie's lap (29 July, p. 308).—I am, etc.,

PHILIP BARKER.

Coroners' Jurisdiction

SIR,—I have read with interest and not a little surprise the letter from Mr. H. A. Kidd (5 August, p. 372) and the two previous letters to which he refers. While not wishing to enter into discussion on the content of any of the Association's evidence submitted to the Brodrick Committee, I feel it is important to put the record straight on the *modus operandi* of submitting the evidence.

As is usual in specialized matters of this kind, Council refers the matter in the first place to one or more of the appropriate committees—in this instance the Private Practice Committee. This committee in turn referred it to its Forensic Medicine Subcommittee, which consists of specialists in this field, including consultant pathologists and police surgeons.

Dr. Ivor Jones (24 June, p. 845) makes it perfectly clear that the Private Practice Committee followed the normal procedure not only with the original report but also with the questionary received from the Brodrick Committee, and that ample opportunity was given to all interested parties to make their views known before Council's final approval. In my opinion, neither the Forensic Medicine Subcommittee nor its parent Private Practice Committee is in any way open to the charge of acting in an autocratic way in this matter.—I am, etc.,

JACK E. MILLER,
Deputy Chairman,
Private Practice Committee.

Glasgow W.2.

Asbestosis

SIR,—The leading article on " Asbestosis " (8 July, p. 62) is opportune. I would draw your attention, however, to a probable, hitherto unpublicized asbestos hazard. For some years past the filter pads of certain respirators have been made of wool-asbestos fibre. It is possible that inhalation of asbestos fibre takes place if such masks are in continuous use. It is also likely that many such filters are still being used.

Masks of this type were tested in 1962 for penetration.[1]—I am, etc.,

L. B. BOURNE.

Psychological Factors and Ulcerative Colitis

SIR,—In your leading article (1 July, p. 1) there is an implied challenge to controversy in relation to the paper of Dr. F. Feldman and his colleagues (1 July, p. 14). These workers find little or no evidence that ulcerative colitis is a psychosomatic disorder and they give no credit to the accumulated evidence over the 37 years since Murray's paper.[1] You comment that this evidence is largely subjective and anecdotal. Every full personal history, though pejoratively labelled an anecdote, is an account of the substance of a man's life. I submit that this belittling of the life story is an impertinence to the patient and to those workers who are not afraid of involvement in psychological or even philosophical problems.

A person is a psychosomatic construct, hence medicine must be psychosomatic, and this means that the sick man needs to be studied both by physical methods and by the use of subjective methods dependent on observation and communication. It is erroneous to ask how the psyche produces somatic disease, because psyche and soma are the names of two aspects of man viewed in two different frames of reference which cannot be brought into such naive causal relationship. But history-taking has another subjective value, personal to the doctor who listens quietly while the patient finds his way through his own resistance up to the expression of his conviction of the relevance of his struggles, hopes, and fears to his somatic manifestations.

There is a great deal of evidence in previous studies of the role of the psyche in ulcerative colitis, of the relation of increasing stress to its onset and relapses, of the moulding of the subject through childhood and adolescence into a personality immature for age, over-dependent and of poor level in social communication, and also of the favourable effects of psychotherapy. Because this evidence is subjective and hence unpalatable to some workers is no reason for ignoring it—this is not a scientific attitude. Professor Groen[2] frankly avowed that he thought Murray's thesis would be easy to disprove, but his patients taught him otherwise. The reluctance to contemplate the role of the psyche is understandable. Medicine preserves the stability of Newtonian physics. Its basic sciences are chemistry, classical physics, and a biology based on these. We therefore prefer mechanical explanations or models which we can comprehend and hypotheses understandable in the light of our training and tradition. The modern physicist is not so bound. He deals with relativity, quantum theory, and uncertainty relations. Because of the latter he accepts that his observations cannot be exact, because there is a subjective element in observing. He does not demand that the phenomena of nature must be explicable within the limits of the present human mind. Cause is no longer a matter of contiguity and sequence of events ; physics is no longer the paradigm of exact science.

It is impossible to analyse the paper of Feldman *et al.* because of paucity of data ; the methods used are barely described though existing in a 200-page work-book. But it can be compared with the paper of O'Connor *et al.*[3] with its use of inventories, interviews, and scoring techniques, *but with entirely opposite conclusions.* Surely this must throw doubt on the validity of these techniques which workers have been compelled to use in order to be " scientific " and " with it." The concept of personality is subtle, but the word itself is useful, like mind or psyche. Can it be measured in these ways ? It would be accepted as impossible to measure the artistic value of a picture by counting categories of brush strokes, lines of tension, or distribution of masses. Similarly a man's life is too rich for methods of analysis which essentially summate factors from a hotchpotch of categories.

The psychosomatic hypothesis of ulcerative colitis is simply stated: the disease is largely determined by stress acting on an immature personality, this latter being the result of social and psychological forces acting during the period of personality development—the " strain " is most evident as the somatic disorder. This, like all hypotheses, cannot be proved but it can be supported or falsified. Its important corollary is the implication of appropriate treatment. It would be naive to consider that maturation of personality can be restored wholly at a time beyond the correct stages for this process. It would be equally naive to expect any psychotherapy to cope with the irremediable reality situations sometimes encountered.—I am, etc.,

HUGH GAINSBOROUGH.

Pericarditis in the Tropics

SIR,—Dr. R. H. Llerandi (1 July, p. 48) and other colleagues have kindly brought to my notice a misleading statement which appeared in my discussion on the treatment of amoebic pericarditis (13 May, p. 423).

The treatment which I have recommended in the article is sound. However, the sentence " Chloroquine is necessary because emetine usually has no effect on hepatic amoebiasis " was an unsuccessful attempt to say something rather different from what appeared in the paper. As it stands, the statement is not true and should be deleted. I regret having given the impression that emetine is of little value in the treatment of hepatic amoebiasis. It is in fact of great value, as shown by Dr. L. Rogers.[1]—I am, etc.,

K. SOMERS.

Sugar Consumption and Acne

SIR,—I was interested in the study by Dr. D. G. G. Bett and others (15 July, p. 153) in which they found raised sugar consumption in patients with seborrhoeic dermatitis but not in those with acne.

In a study of 2,720 soldiers it was established that there is no correlation between the incidence or severity of acne and dandruff.[1] There was also no correlation between acne and obesity in men under 20 years old—the age group studied by Bett *et al.* However, in older men (age 20–40) there was a significant correlation between acne and obesity. It appears, therefore, that perhaps Bett *et al.* should extend their study to see if there is raised sugar intake in this older group before it can be settled that sugar intake in acne is not raised.—I am, etc.,

Sliding Board for Severely Disabled Patients

SIR,—It is good to read in your issue (22 July, p. 244), Miss M. J. Seiffert's appreciation of the use of a sliding board for severely disabled patients in Britain. It has been popular in Australia for a considerable length of time. Perhaps some constructive comments from one who has seen this method in use by a near relative for many years will be acceptable.

In the first place, a board which is ¾ in. (2 cm.) thick is difficult to introduce under a patient's buttocks, by a second party in particular. A thinner board in 5-ply will support a 12-stone (76-kg.) man. A board which is only 2 ft. 6 in. (75 cm.) long is too short for use in a London taxi. A longer, lighter board can be carried around without any great inconvenience.

A short board, say 2 ft. (60 cm.) long or so, is particularly useful for getting on and off lavatory seats because it is not so liable to catch the edges of the plastic or wooden top.—I am, etc.,

R. E. JOWETT.

The Royal Infirmary,
Sunderland.

Is Anaesthetist Dentist's Agent?

SIR,—I was very interested to read Dr. A. M. Danziger's letter (29 July, p. 310). It raises a very pertinent point. Why should a patient not contract with an anaesthetist privately to give an anaesthetic to himself, and at the same time contract with a dentist to have treatment under the National Health Service?

There are a number of people (children and adults) who cannot, for various reasons, accept conservative dental treatment without going to sleep; but it is unrealistic to expect a specialist to spend hours giving endotracheal anaesthesia without adequate financial reward, as is the case at present.

In view of the recent recommendations that dental anaesthetics should be given by specialists[1] then it is only reasonable that realistic anaesthetic fees should be paid, not only for extractions, etc., but for conservative work as well.—I am, etc.,

Barrow-in-Furness. R. IAN DIXON.

Opportunities in British Medicine

SIR,—I am surprised that the advertisement sponsored by the Ministry of Health (15 July) on the above subject has provoked little comment. Directed toward the emigrant doctor, an interview board is to tour Canada and the U.S.A. in an attempt to attract doctors back to Great Britain.

"Payment of fares to selected applicants is authorized." Surely once a doctor has lifted his roots and faced life in a new country he is going to expect a guaranteed career structure as well, not only a free journey. Even the Ministry cannot expect to secure labour without being able to offer such a guarantee.

How can people abroad be offered posts in Britain and a progressive career? Are we going to apply for advertised vacancies to find appointments being made "in absentia"? There is enough time wasted by applicants travelling to interviews for posts which practically do not exist, as either a local man has been promised the vacancy or errors were made in the advertisement, which is not uncommon. Now it looks as though the additional factor of absent successful candidates has to be faced.

What career opportunities are available for those who remain? In a few weeks' time I personally may have to face a period in another specialty or general practice, in order not to be unemployed, until a post required for examination purposes becomes available. This is hardly "opportunity." While an effort must be made to attract doctors back to this country, it must not be made to the detriment of those who have remained, carrying the extra work load caused by colleagues leaving.

Last year I wrote in these columns (20 August, p. 470) about the future of junior staff, and asked could anyone see a future for us. No one has said "Yes" to this question. It looks as though the answer is to emigrate first, then the Ministry will offer a free passage home and career opportunities, which must carry some degree of guarantee.

I cannot help feeling that the activities of this interview board will need careful watching by our Junior Hospital Staffs Group. Any advantages offered to emigrants over staff who have remained in Britain must be opposed. It need hardly be stated that if conditions were good there would be no need to tempt anyone back.—I am, etc.,

Queens Park Hospital,
Blackburn. D. C. PRIOR.

Seniority Allowance

SIR,—I qualified from Madras Medical College, India, in 1949 and have been in general practice (N.H.S.) since 1954. Unfortunately I failed to register in this country until 1954, although my qualification is recognized by the G.M.C.

My recent application for seniority allowance was turned down by the Ministry on the grounds that "registration with overseas bodies does not count for the purpose of determining eligibility for seniority payments."

I consider this a gross injustice, especially as doctors who qualified in the Republic of Ireland are now eligible for this payment. —I am, etc.,

Coseley. A. M. POORNAN.

Seniority from 1913?

SIR,—May I draw attention to the often parlous plight of many retired "panel" general practitioners who have worked for many years in the admittedly underpaid service, often, as in my own case, from the inception of the N.H.I.—that is, 15 January 1913.

Could not some of the monies which were to have been paid for seniority awards be given to the elder pensioners so that each receives a minimum of £10 a week? I have never seen it stressed that the year 1988 will come before any general practitioner retires on "half-pay"—the "half-pay" one reads about in novels that the retired Army and Navy officers retire on. Did they have to wait 40 years?—I am, etc.,

Minehead,
Somerset. EGERTON C. WHITE.

Points from Letters

Self-expulsion of a Nasal Polyp

Dr. J. M. CRAWFORD (Chertsey, Surrey) writes: I do not know if it is a common occurrence to expel a nasal polypus from one's nose as Dr. B. Green's patient did (5 August, p. 372).

If it is of any interest to him, or others, I managed to do this myself at the age of 6. I was in bed with a cold at the time and I can tell that I was more than a little upset. I thought that I had literally blown my brains out.

Errors Caused by Language Barriers

Dr. E. V. BEVAN (Cambridge) writes: I read recently (daily press, 25 May) of the tragic mistake in a hospital where the wrong leg was amputated from a patient. The surprising thing is not that this should happen at all but that it does not happen every day. In very many hospitals a situation may arise where the nurses are Italian or Spanish, the registrar is a Nigerian, the houseman a West Indian or a Malaysian, and the patient a Glasgow Scot. How on earth any communication between this cross-section of the United Nations can take place at all is very difficult to understand.

Obituary Notices

THOMAS JOHN HENNELLY
M.D., D.P.M.

Dr. T. J. Hennelly, former physician superintendent of Whitchurch Hospital, Cardiff, and lecturer in psychological medicine at the Welsh National School of Medicine, died on 21 July. He was 63.

Thomas John Hennelly was born in Western Ireland on 7 June 1904, and received his medical education at Galway and Dublin, graduating M.B., B.Ch. B.A.O. with first-class honours in 1928. After a short time in general hospitals and in general practice he entered the field of psychological medicine in June 1929, holding appointments at Gloucester County Mental Hospital, Powick Hospital, Worcester, Brookwood Hospital, Surrey, and the West End Hospital for Nervous Diseases, London. He took the D.P.M. in 1931 and proceeded M.D. the following year. In May 1933 he was appointed senior assistant medical officer at Whitchurch Hospital, Cardiff, and became the deputy physician superintendent in 1934. In 1937 he was appointed at the early age of 32 to the position of physician superintendent, and remained at Whitchurch in this capacity until his retirement from the National Health Service in December 1959. He then emigrated to Canada, and was appointed director of the Center Lawn Hospital, Essondale, British Columbia, until his final retirement in July 1966. He returned to Britain and went to stay with an old friend and colleague at Woodbridge, Suffolk.

He took a keen interest in the Royal Medico-Psychological Association, and had been chairman of the South-western Division and secretary of the research and clinical section. He was president of the section of psychiatry at the Annual Meeting of the British Medical Association in 1953.

Tommy Hennelly was a great character with dynamic personality, keen sense of humour, of philosophical outlook, a first-class clinician, a profound reader, and he loved nothing better than a good argument. He retained his Irish brogue, and was known by his students as "tic and tin." The hospital nursing staff knew him affectionately as "father." Outside his work he read avidly books of an autobiographical and historical nature. A man of firm opinion who never curried flattery or sought any favours, he was highly esteemed by all those who worked with and under him.

His wife, Dr. Margot Hennelly, predeceased him by three years. There remain their five children, Michael, Mary, John Angela, and Dermot, to whom we extend our deepest sympathy.—A. C.

P. W. HAMPTON, M.D.

Dr. P. W. Hampton, formerly consultant surgeon to Noble's Isle of Man Hospital, died at his home in Governor's Road, Onchan, Isle of Man, on 1 July, at the age of 91.

Percy William Hampton was born on 22 March 1876, and received his medical education at the University of Edinburgh, graduating M.B., Ch.B. in 1899. He served as civil surgeon to the South African Field Forces in 1901–2. Returning from South Africa, in 1905 he proceeded M.D. with high commendation. He engaged in general and consulting practice in the Isle of Man, and in 1913 joined the staff of Noble's Isle of Man Hospital as honorary assistant surgeon. During the first world war he served in the R.A.M.C., with the rank of major, as surgical specialist at the Military Hospital at Ripon, Yorkshire. After demobilization he returned to the Isle of Man, but in 1927 ill-health obliged him to relinquish general practice, though he continued his work as honorary surgeon at Noble's Isle of Man Hospital. In 1944 he became honorary consulting surgeon to the hospital, a position he held until the introduction of the Manx National Health Service in 1948. In 1944–5 he was a representative at the Annual Meeting of the British Medical Association. He was appointed vice-president of Noble's Isle of Man Hospital in 1944, an office he held until October 1964, when the hospital was transferred to the Isle of Man Health Services Board.

A colleague writes: Both in his general practice and in his hospital work Dr. Hampton rendered outstanding service to the island of his birth. A capable all-round diagnostician, and an excellent surgeon and obstetrician, he also acted as surgical referee to the Isle of Man National Health Insurance Board, and was one of the outstanding medical personalities of the island.

He is survived by his widow, who nursed him devotedly for several years, and by two daughters, both doctors, and both married to members of the profession.

J. BROADFOOT, M.D., D.P.H.

Dr. J. Broadfoot, formerly a general practitioner in Ross-shire, died suddenly in hospital in Inverness on 13 July after a short illness. He was 80.

John Broadfoot was born in Hamilton, Lanarkshire, on 13 April 1887, and was educated at Glasgow High School and University, where he graduated M.B., Ch.B. in 1910. He held resident posts of house-physician and house-surgeon in the Western Infirmary, Glasgow, and acted for a time as a demonstrator in anatomy at the University. In 1913 he took over the practice in Dingwall of the late Dr. John Adam, and remained there for 27 years. He was medical officer to the Ross Memorial Hospital, Dingwall. For ten years he was a member of Ross County Council and of the Education Authority. In 1921 he proceeded M.D., and in the same year took the D.P.H. In 1930, seeking a change from the incessant strain of a busy practice, he was appointed assistant medical officer of health in Inverness. In 1935 he became a family physician again, and took up practice in Kilmacolm, Renfrewshire. He remained there until after the second world war. He retired in 1945 and went to live in Conon Bridge, Ross-shire, where he took a keen interest in the life of the village and in a wide variety of local causes. After his retirement from general practice he made several voyages as a ship's surgeon, and visited India, China, Australia, and South Africa.

The major part of Dr. Broadfoot's professional life was spent in Ross-shire, where he was a most popular and much respected doctor. A Ross-shire paper recalls that "weather never deterred him on his errands of mercy; when his car would go no further, he waded waist deep through snow-drifts to reach a sick-bed." He was always a brisk and energetic man. His somewhat abrupt and gruff manner was discounted by the twinkle in his eye, and could not conceal his underlying kindness. His main recreations were golf and bridge.

He is survived by his wife, a son, and two daughters. The son is in practice in Port Glasgow, and one daughter practises in Hampshire with her husband.—A. J. C. H.

H. SIMMONS, M.R.C.S., L.R.C.P.

Dr. H. Simmons, a general practitioner in Langley, Bucks, died in St. George's Hospital, London, on 22 July, aged 60.

Harry Simmons was born in London on 6 January 1907, and received his medical education at St. Bartholomew's Hospital, London. He qualified with the Conjoint diploma in 1931, and held hospital posts at the Royal Hospital, Richmond. After a period in general practice he joined the R.A.M.C. at the outbreak of the second world war, and served throughout. On demobilization he found that his practice no longer existed, and he settled in practice at Langley, at first in partnership and then alone. His country practice, however, changed in character as the district developed, and Harry Simmons, helped by his devoted wife, rose to the challenge and built a general practice service for a thickly populated area, with modern surgeries, taking on partners, and above all still caring for individual patients with the same regard and devotion to their welfare as he had done in his small country practice.

He had more than his share of ill-health, but he never gave in to it, and showed at all times boundless energy and interest in his work, refusing to give anything less than his best. He never lost an opportunity of helping a patient or a colleague, and did so quietly and with charm.

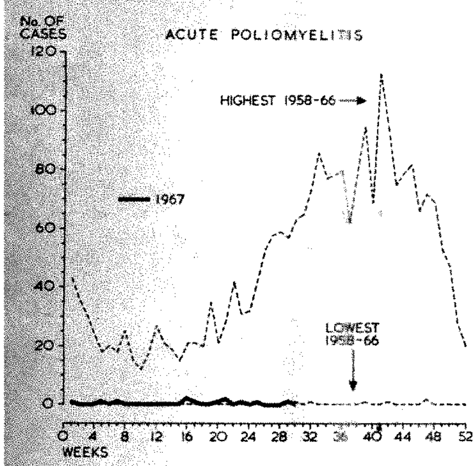
He leaves a widow, a daughter and her family, and a son, also a doctor, to whom our deepest sympathies are extended.—J. R. and N. G.

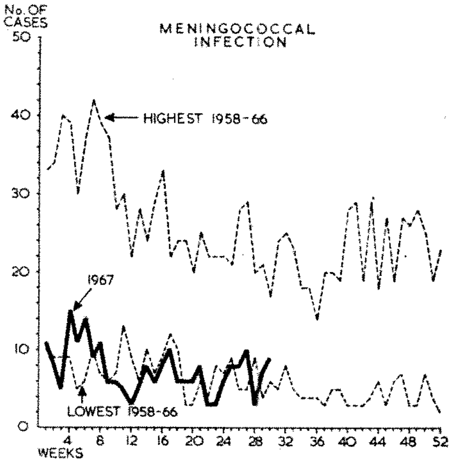
News and Notes

EPIDEMIOLOGY

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of acute poliomyelitis and meningococcal infection in England and Wales. Figures for 1967 are compared with the highest and lowest figures for each week in the previous years shown.





Infectious Diseases

Areas where numbers of notifications were high in the latest two weeks for which figures are available.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending **29 July** (No. 30) and corresponding week 1966.

Figures of *cases* are for the countries shown and for Greater London. Figures of *deaths* and *births* are for the whole of England and Wales (London included), Greater London, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

MOTORING

Synchromesh, and How to Use It

[FROM OUR MOTORING CORRESPONDENT]

Progress in motor-car design can sometimes take the form of a sudden advance resulting from an invention, but is more often painfully achieved by a great deal of intelligent experimental work. The history of synchromesh illustrates both these processes, and is also interesting because of the continued importance of synchronizing mechanisms in gearbox development.

The primitive kind of gearbox first used by Panhard and Levassor was adequately described by the inventors in the immortal phrase "It's brutal, but it works." Changes of ratio were made by sliding one gear into mesh with another and, as the speeds were different, a special trick called "double declutching" was needed in order to avoid destructive clashes between the gear teeth. By varying the speed of the engine and briefly re-engaging the clutch with the gearbox in neutral, the driver was able to match the peripheral speeds of the gears, after which they could be brought into mesh without shock or noise.

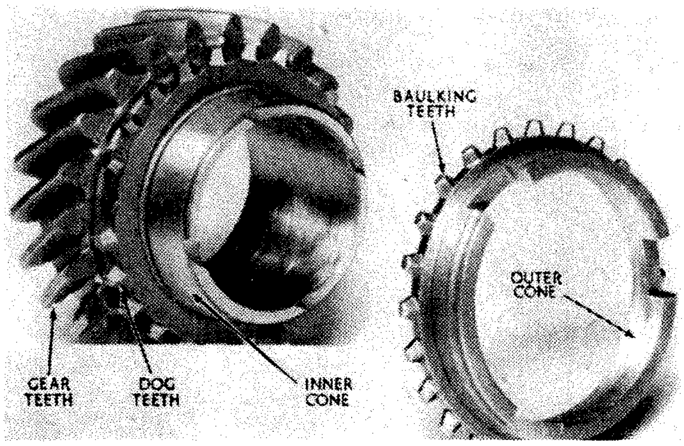

FIG. 1.—A gear wheel with dog teeth and synchromesh cone (left); the mating cone and baulking teeth are seen on the right.

Expert drivers found pleasure in exercising their skill in changing gear, but to the inexpert it remained a difficult and irritating process. There was also an element of risk when trying to change down on a steep ascent because the driver who failed to engage the gears could find himself in neutral with the car commencing to run backwards.

In the late 1920s a basic change occurred in gearbox design which paved the way for the subsequent introduction of synchromesh. Instead of sliding one gear into mesh with another, each pair of gears ran constantly in engagement but one of them was freely mounted on its shaft. A sliding member, called a dog clutch, enabled the "free" gear to be rotationally coupled to the shaft at the will of the driver. In this way the wear and tear caused by inexpert gear changing was transferred from the gear teeth to the more robust teeth of the dog clutches, but damage and noise could still result if the driver was unable to pre-adjust the rotational speeds by the double declutching process.

Several inventors then applied their minds to finding ways in which the rotational speeds could be synchronized automatically, and eventually this was done by bringing together the inner and outer cones of a small friction clutch before meshing the dogs themselves. Running in oil, the cones could slip without harm until their speeds were synchronized, after which the dogs could be engaged without difficulty. Of course the processes of frictional and positive engagement had to occur smoothly and consecutively as the driver moved the gear lever from one position to another, and this was easier to define than to achieve.

Much experimental work was necessary in order to arrive at the most favourable cone angles, surface finishes, and materials required for smooth (yet rapid) synchronization and a reasonable "life." The first production gearbox embodying synchromesh was offered by General Motors in a Cadillac in 1930, shortly followed by Vauxhall in England. A current Vauxhall design is shown in Fig. 1.

In spite of the universal use of synchromesh in manual gearboxes today, many drivers regard it as something of a mystery. Although simple in principle, the mechanism is difficult to describe or illustrate. But by explaining how it works rather than how it is designed I hope to be able to clear up some misunderstandings and causes of misuse.

Reduced to the simplest terms, the diagram (Fig. 2) shows the principal parts of a car transmission system. Note that although shafts A and B are in line, they are separate components which are disconnected within the box when the gear lever is in neutral. Another means of disconnecting the drive is by depressing the clutch pedal, which frees the friction grip normally applied to the clutch disc. Note, also, that shaft B is permanently connected to the back axle by the propeller shaft (not shown).

Now suppose that a car is travelling at 35 m.p.h. in top gear with the engine (and shaft A) turning at about 2,000 revs. per minute. Top gear is "direct," so that the speed of shaft B will also be 2,000 revs. per minute.

Changing Gear

The driver now decides to change down into third gear, to enable the engine to run faster in relation to the speed of the car and so to provide more power for climbing a gradient or for overtaking. It can be assumed that the change is made so quickly that the car loses very little speed during the process—in other words, that shaft B continues to turn at 2,000 revs. per minute or thereabouts. The sequence of events is as follows:

(1) Clutch pedal is depressed, disconnecting engine from clutch shaft A.

(2) Gear lever is moved into neutral, disconnecting shaft A from shaft B within the gearbox.

(3) Gear lever is moved towards the third gear position, bringing two synchromesh cones into contact.

(4) The mating cones enable shaft B to accelerate shaft A to a rotational speed determined by the third speed gears (say 2,800 revs. per minute), the clutch being still disengaged.

(5) Gear lever movement is completed, engaging dog teeth and so providing a positive drive (through the gears) between shafts A and B.

(6) Clutch pedal is released and engine speed is raised to 2,800 revs. per minute. Note that practised drivers will already have increased the speed of the engine appropriately (by using the accelerator) during the gear-changing process.

The clue to an understanding of this train of events is that it is the momentum of the moving car, acting through the wheels, back axle, propeller shaft, and shaft B, which drives the cones and gears while they are disconnected from the engine by the clutch. This applies equally to an upward gear-change, in the course of which the cones *slow down* shaft A in relation to shaft B before the engagement of the dog teeth.

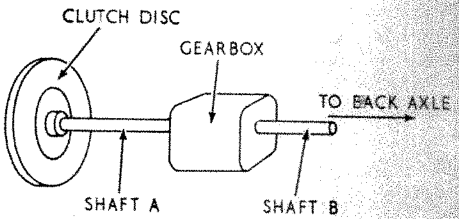

FIG. 2.—Car transmission system; the speed ratio between shafts A and B depends on the gears selected within the box.

The work done by the cones is therefore confined to altering the speed of relatively light gearing and shafting plus the clutch disc, which (though also light in weight) has considerable inertia because of its diameter. However, this is what the cones are designed to do, and they should survive thousands of engagements without appreciable wear. If they deteriorate early in life it is usually due to clutch drag; in other words, the disc is not completely free during the gear-changing process and consequently the cones have to overcome an unpredictable amount of frictional resistance.

There are various causes for clutch drag. Some drivers form the bad habit of not depressing the clutch pedal fully, so that the spring load on the disc is not completely relieved. In other cases the hydraulic device often used to connect the clutch pedal to the clutch fork may be at fault (owing to fluid leakage or ingress of air), so that the movement of the fork is inadequate even though the pedal is fully depressed. A disc that has become distorted by undue slipping in traffic (and consequent high temperature) may not be able to run completely free, even if the full withdrawal movement is being attained.

A more subtle cause of cone wear is sometimes traceable to the misguided attempts of a driver to "help" the synchromesh mechanism by inexpert double declutching. For example, if he grossly over-speeds the engine in neutral during a downward change, with the clutch temporarily engaged to accelerate the disc and shaft A, the cones may find more work to do in correcting his mistake than in their normal unassisted duty.

My advice is to let the synchromesh mechanism do the job for which it was designed while ensuring that the clutch is completely free during the process. As soon as the gear-change has been completed a smooth re-engagement of the clutch will be assisted if the engine has been accelerated during a downward change (but not too much) or allowed to lose speed during an upward change.

All modern synchromesh mechanisms embody a baulking device, intended to prevent premature dog engagement, but for the best and most consistent results it is advisable to apply a steady but not excessive pressure to the gear lever and to complete the change at one hit without hesitating part-way. This ensures that the cones do their job before the dog teeth slide into mesh.

MEDICO-LEGAL

Immigrants' Rights of Appeal

[FROM OUR LEGAL CORRESPONDENT]

The Divisional Court of the Queen's Bench Division refused[1] to intervene after an immigration officer had refused to allow an Indian into the country on medical grounds, despite a refusal by the Secretary of State to allow him an opportunity to rebut the medical evidence.

Avtar Singh arrived in England on 4 July to marry his fiancée, who was already in this country. On arrival he was examined by a medical inspector and refused admission. On 11 July the Home Office stated that after an examination by two medical inspectors the immigration officer formed the view that Singh was suffering from mental disorder. The mental disorder referred to was "subnormal mentality."

The Court held that as Singh had no right of entry into the country the immigration officer had an unfettered discretion to refuse admission without giving reasons. If he chose to give reasons, that did not give the would-be immigrant any right to rebut those reasons. The position might be different where the would-be immigrant had a right of entry subject to the possible grounds of objection referred to in Sections 2 (2) and 2 (3) of the Commonwealth Immigrants Act, 1962.

Subsequently, the Court of Appeal agreed to an expedited hearing of an appeal from the Divisional Court's decision, but the appeal was abandoned before the day fixed for hearing (31 July) and Singh returned to India.

MEDICAL NEWS

New Medical School for Southampton

A joint statement by the Department of Education and Science and the Ministry of Health says that the Government has decided to authorize the construction of a new medical school at Southampton University in conjunction with the Southampton General Hospital. Planning of the rebuilding of the hospital has started, and work on the medical school buildings should begin early in 1969. The school is at present being planned for an entry of 130 medical students a year.

The Royal Commission on Medical Education and the University Grants Committee have been consulted about this development and approved of its beginning before the Royal Commission's report, which is expected by the early part of 1968.

Committee on L.S.D. and Cannabis

The members of the subcommittee of the advisory committee on drug dependence set up by the Home Office and the Ministry of Health to consider L.S.D. and cannabis are: LADY WOOTTON OF ABINGER (chairman), Mr. K. J. P. BARRACLOUGH (chairman, Poisons Board), Dr. T. H. BEWLEY, Mr. P. E. BRODIE (Assistant Commissioner, Metropolitan Police), Dr. P. H. CONNELL, Dr. J. D. P. GRAHAM, Dr. N. B. MALLESON, Mr. H. W. PALMER (general manager, Glaxo Group), Mr. TIMOTHY RAISON (editor, *New Society*), and Mr. MICHAEL SCHOFIELD (research worker in sociology, Nuffield Foundation).

New M.R.C. Research Unit

The Medical Research Council is to set up an immunochemistry research unit at Oxford University under the honorary direction of Professor R. R. PORTER, F.R.S., who will take up his appointment as Whitley Professor of Biochemistry in the University on 1 October. The new unit will expand the work of the Council's research group in immunochemistry at St. Mary's Hospital Medical School, London. Its work will be concerned with elucidation of the structure of antibodies and the relationship of their structure to their function.

Anglo-French Exchange Bursaries

Applications are invited for the bursaries which will be awarded in 1968 to young British doctors under the exchange scheme arranged by the French Embassy in London between the Institut National de la Santé et de la Recherche Médicale in Paris and the Ciba Foundation in London. The value of the French grants is 1,400 F. a month tax free, and they will be awarded for periods of two to four months to medical men who wish to obtain clinical experience or carry out research in France. Details from Dr. WOLSTENHOLME, Director, Ciba Foundation, 41 Portland Place, London W.1. The closing date for applications is 15 October.

N.H.S. Research Projects

A grant of £4,772 for two years for studies of hospital cross-infection has been made to Dr. P. N. EDMUNDS, Fife District Laboratory, Windygates, Fife, and Dr. R. RANKIN, Group Laboratory, Royal Infirmary, Stirling. This is one of six grants for medical research approved by Mr. WILLIAM ROSS, Secretary of State for Scotland, on the recommendation of the Advisory Committee on Medical Research in Scotland. Others to receive support for projects are: Professor W. D. McHUGH, Department of Dental Health, University of Dundee, continuation of epidemiological studies of the long-term effects of dental education, £1,800 for two years; Dr. J. A. MILNE, Department of Dermatology, Glasgow University, continuation of a study of pigmented skin lesions, £1,500 for two years; Dr. H. F. V. RIDDLE, Ardclinis, Dysart, Fife, one-year study of fungal respiratory disease, £800; Dr. L. DUNCAN, Diabetic and Dietetic Department, Royal Infirmary, Edinburgh, serum fucose response in diabetics, £1,100 for two years; and Dr. T. ANDERSON, Department of Biochemistry, Glasgow University, cancer research, £2,000 for one year.

Pregnancy Tests

In a letter to hospital authorities the Ministry of Health states that two reagents (Pregnosticon and Prepuerin) used in immunological tests for pregnancy are now available to hospital pathology departments on central supply. These tests are considered to be as reliable as the Hogben toad test. The Ministry recommends that pathology laboratories should accept requests for pregnancy tests on referral from general practitioners. (See leading article, p. 448.)

Inquiry on Elderly Patients

Allegations of ill-treatment of elderly patients made in the book *Sans Everything* will be investigated in private by independent committees, the Ministry of Health said in a statement last week (see *B.M.J.*, 22 July, p. 250). Queen's Counsel will act as chairmen, other members being a doctor, a nurse, and at least one lay man or woman. No member of a committee will have connexion with any hospital authority in the region in which the hospital concerned is situated. The statement contains an assurance that patients and staff will be able to give evidence "in complete confidence." Persons named will hear the allegations and have the opportunity of defending themselves. The Minister proposes to publish the findings and recommendations of the committees, also the names of the hospitals, when the investigations have been completed. (See review of *Sans Everything* at p. 484.)

"British Medical Index"

The medical department of the British Council announces that the *British Medical Index* succeeds the *Indice Medico*, which was prepared and issued by the British Council office in Italy for the past 20 years. The quarterly *Index*, as before, will be arranged alphabetically by periodical title, as abbreviated in *World Medical Periodicals*, the contents of the issues of a periodical included in a particular *Index* being arranged in a continuous sequence in page order. Some selection will be made. Brief congress reports and news items will be omitted, as will correspondence, except letters published in the *British Medical Journal* and the *Lancet* referring to new work or giving important supplementary information about articles already published in these journals.

Meeting in South Africa

The 46th South African Medical Congress, held at the University of Natal, Durban, from 17 to 22 July, was attended by a number of overseas visitors, including Mr. ROBERT V. COOKE, President of the British Medical Association and a vice-president of the congress. Speaking at the end of the meeting, Dr. N. R. POOLER, President of the Medical Association of South Africa, said that many delegates had described the congress as an outstanding one. He was sure, he said, that the South African medical profession had benefited greatly by the visit of their overseas colleagues.

Formation of Audiology Group

An audiology group, open to members of the Society of Medical Officers of Health, is to be set up, with Dr. MARY SHERIDAN as honorary president. It will form a subgroup of the school health services group of the Society. Inquiries should be sent to Dr. L. SOLOMON, Castle Road Clinic, 15 Castle Road, Torquay, Devon.

Report on War Pensioners

At the end of 1966 the Ministry of Social Security was paying 595,000 war pensions at a cost of about £117m. a year. The total was made up of 435,400 disablement pensions, 119,300 widows' pensions, and 40,800 pensions for parents, orphans, and other dependants. In England and Wales some 2,830 pensioners were being treated as in-patients in National Health Service hospitals. The report gives details of limbs and appliances supplied by the Ministry of Health. These included about 3,500 legs and arms, 600 artificial eyes, and more than 9,000 surgical boots. The number of invalid chairs and tricycles in use was 4,300. During the year 579 pensioners received a motor car for the first time. The report refers to the planning of new artificial limb and appliance centres that are to be built in hospital grounds to ensure close association with orthopaedic and rehabilitation services. (H.M.S.O., 8s. net.)

Social Education of Young People

In May this year the Ditchley Foundation arranged a conference, chaired by the DUKE OF EDINBURGH, on the training and use of young people for rescue, first aid, and other forms of service. Participants included members of the medical profession. A summary of the proceedings has now been published in the form of a preliminary report. Copies can be obtained from the Medical Commission on Accident Prevention, 50 Old Brompton Road, London S.W.7, price 5s. plus 6d. postage.

Dr. N. R. Pooler (left) and Mr. Robert Cooke at the civic welcome during the recent South African Medical Congress in Durban.

British Pharmacopoeia Commission

From 29 August the address of the offices and laboratory of the British Pharmacopoeia Commission will be 8 Bulstrode Street, London W.1 (telephone 01-935 7604).

People in the News

▶ Dr. ERASMUS BARLOW has been appointed chairman of the London branch of the Mental Health Research Fund.

News in Brief

A new division of virology has been established at Leeds University within the department of bacteriology under the headship of Dr. JAROSLAW CZEKALOWSKI, senior lecturer in the department.

The Medical Research Council's unit for experimental investigation of behaviour, in the department of psychology, University College, London, has been renamed Unit for Research on Neural Mechanisms of Behaviour. Professor G. C. DREW is honorary director of the unit and Dr. I. S. RUSSELL has been appointed deputy director.

From 1 November the sale of celluloid toys is prohibited under regulations made by the Home Secretary, also the sale of toys coated with paint that contains more than 1.1% of lead.

"Help the Disabled Week" will be held this year from 2 to 8 October. The purpose is not to raise money but to encourage acts of consideration.

The Association for Spina Bifida and Hydrocephalus has opened its first full-time office at Benjamin Franklin House, 36 Craven Street, London W.C.2.

Grants and Awards

Dr. D. J. WEATHERALL, of the Nuffield Unit of Medical Genetics, Liverpool University, has been awarded a grant of $1,000 a year for two years by the World Health Organization in aid of a study of haemoglobin synthesis in thalassaemia. It will be a joint study by the Nuffield Unit of Medical Genetics and the Haematology Research Group at the Siriraj Hospital, Bangkok.

A grant of £2,500 a year for a minimum period of five years has been made by the trustees of the Astor Foundation to the College of Pathologists to finance a research fellowship in experimental pathology. The fellowship is to be designated "The Astor Research Fellowship."

The National Fund for Research into Crippling Diseases has made grants totalling £20,000 to the University of East Africa, Makerere, Uganda, to support research to help the disabled.

Coming Events

Hackney Hospital, London.—Course for general practitioners, September to December. Details from Mr. M. F. PILCHER, F.R.C.S., Clinical Tutor.

Royal Medical Benevolent Fund.—Annual general meeting, 5 September, 5 p.m. Medical Society of London, 11 Chandos Street, London W.1.

Leukaemia Research Fund.—Annual guest lecture by Professor H. S. KAPLAN (Stanford University, California), "On the Natural History of the Murine Leukaemia," 19 September, 5.30 p.m., Institute of Child Health. Admission by ticket, obtainable from Secretary, Medical Advisory Panel, Leukaemia Research Fund, Institute of Child Health, Great Ormond Street, London W.C.1.

King Edward's Hospital Fund for London.—Conference, "Design of Hospital Bedsteads," 28 September. Details from Mr. IRFON ROBERTS, Hospital Centre, 24 Nutford Place, London W.1.

London Nursing Exhibition and Conference.—16–20 October, Seymour Hall, London. Details from Mr. DEREK PAGE, Dorset House, Stamford Street, London S.E.1.

Cambridge University Medical School.—Symposium, "Old Age and Anaesthesia," 28 October, Addenbrooke's Hospital. Fee £1 1s. Applications to Secretary, the Medical School, Tennis Court Road, Cambridge.

Societies and Lectures

For attending lectures marked ● a fee is charged or a ticket is required. Applications should be made first to the institution concerned.

Wednesday, 23 August

STOKE MANDEVILLE HOSPITAL.—(1) 12.15 p.m., Dr. A. O. Robson: Some Aspects of Bronchial Asthma. (2) 6 p.m., Dr. M. Ikram: Malabsorption Syndrome.

Friday, 25 August

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. H. Nicholson: clinical demonstration.

Appointments

MANCHESTER REGIONAL HOSPITAL BOARD.—J. C. J. L. Bath, M.B., M.R.C.P.Ed. (whole-time or maximum part-time consultant physician, Bolton and District group of hospitals); A. Ashworth, M.B., F.R.C.S. (consultant urologist, South Manchester group of hospitals—nine half-days weekly); E. A. Shaw, M.B., F.F.A. R.C.S., D.Obst. R.C.O.G. (whole-time consultant anaesthetist, Salford group of hospitals); F. R. Glover, M.B., D.P.H. (whole-time or maximum part-time consultant physician in geriatrics, Bury and Rossendale group of hospitals); Kathleen M. Watson, M.B., F.F.A. R.C.S. (whole-time consultant anaesthetist, Oldham and District group of hospitals); W. R. Grundy, M.B., D.M.R.D. (whole-time or maximum part-time consultant radiologist, South Cheshire group); W. G. Brown, M.B., M.C.Path. (whole-time or maximum part-time consultant pathologist, North Manchester group of hospitals).

NORTH-WEST METROPOLITAN REGIONAL HOSPITAL BOARD.—H. Westbury, M.B., M.R.C.P., F.F.R., D.M.R.D. (consultant radiologist, Harefield and Mount Vernon Hospitals); F. S. Busaidy, M.B., D.O. (assistant ophthalmologist (medical assistant grade) Royal Northern Hospital and School Eye Clinics); R. P. M. Urquhart, M.B., D.P.M. (consultant child psychiatrist, Uxbridge Child Guidance Clinic, Hayes Child Guidance Clinic, and Hillingdon Hospitals); J. L. McClure, M.B., M.R.C.P., D.P.M. (consultant psychiatrist, St. Bernard's Hospital and Ashford Hospital); L. Kreel, M.B., M.R.C.P., F.F.R., D.M.R.D. (consultant radiologist, District Hospital and Clinical Research Centre, Northwick Park).

UNITED BIRMINGHAM HOSPITALS.—P. W. Dykes, M.D., M.R.C.P., M.R.A.C.P. (consultant physician to the United Birmingham Hospitals); G. Hall Davies, M.B., F.F.A. R.C.S., and J. S. Mather, M.B., F.F.A. R.C.S. (joint appointments of consultant anaesthetists to the United Birmingham Hospitals and the Birmingham Regional Hospital Board).

Universities and Colleges

CAMBRIDGE

M.D.—A. M. Fisher, M. H. Davies, J. E. Stark, R. Schram.

M.CHIR.—*T. J. S. Patterson.

M.B., B.CHIR.—*G. A. H. Buttle.

M.B.—*K. G. E. Brown, *R. J. G. Irons, *T. A. Trevelyan, *J. R. Shelley, *C. W. G. Redman, *J. R. Sibert, *J. S. Yudkin, P. H. Gentle, *C. A. Ellison, R. Lendrum, *A. J. W. Hilson, N. J. Ireland, J. B. Endacott, C. S. Kolb, *Patricia M. Martin, *Margaret S. Povey, *(Mrs.) Gillian D. Yudkin, *Harriet M. Hargreaves.

*By proxy.

LONDON

Mr. Ian McColl, lecturer at Guy's Hospital Medical School, has been appointed to the readership in surgery tenable at St. Bartholomew's Hospital Medical College.

M.D.—S. E. H. Brooks.

MANCHESTER

Appointments.—Dr. Elizabeth B. Butler (senior lecturer in cytology (cellular pathology), Department of Pathology); Dr. N. P. Mallick (lecturer in medicine); Dr. L. Forrest and Dr. K. W. R. Tuson (assistant lecturers in physiology).

BIRMINGHAM

In Congregation on 7 July the following degrees were conferred:

M.D.—[1]K. Horsfield, W. I. H. Shedden, [9]N. Segel.

PH.D.—*In the Faculty of Medicine:* Susan Johnson, [9]B. N. Sharma.

M.B.—[1 2 4]J. R. Jackson, [3]C. P. Abson, [3]I. Appleyard, [3]D. G. Arkell, [3]J. E. Bent, [3]M. Berry, [3]W. P. Beynon, [3]E. M. Botheroyd, [3]B. J. Boughton, [3]P. J. Bradwell, [3]A. C. D. Brown, [3]Rosemary A. Brown, [3]Gwynneth I. Buchan, [3 5]Jennifer N. Bulman, [3]R. Burford, [3 6]D. J. Campbell, [3]D. F. Child, [3]N. M. Chitimba, [3]Mary R. Churchill, [3]P. R. Cleland, [3]A. G. Cohen, [3]M. R. Cooper, [3]Christine P. Cowell, [3]L. S. Culank, [3]M. J. R. Donovan, [3 4 6]Jennifer Faid, [3]M. J. Y. Fisher, [3]J. F. Forrest, [3]D. I. M. Forster, [3]T. A. French, [3]Carole A. Frost, [3]J. G. Geater, [3]R. H. George, [3]M. R. Glass, [3]T. P. Goh, [3]H. D. Graham, [3]R. C. Hall, [3]Diana G. Hawkes, [3]R. E. D. Henebury, [3]M. A. Hughes, [3]T. B. J. Hughes, [3]A. P. F. Jackson, [3]C. M. Jones, [3]D. W. Kett, [3]Gillian A. Kings, [3]Margaret E. Kirkwood, [3]Arabelle M. Larkinson, [3]G. T. Lealman, [3]S. I. Lewis, [3]I. W. McCall, [3]D. L. MacDonald, [3]Kathleen M. Mackrodt, [3]J. J. McMillan, [3]D. T. Milledge, [3]Rosemary Moore, [3]Ann O'Donovan, [3]Gillian R. Osborn, [3]M. J. Ostrowski, [3]Ruth Ostrowski, [3]E. P. Owens, [3]M. Pabari, [3 7]N. A. J. Pereira, [3]A. P. Riley, [3]Gabrielle Round, [3]S. R. Sales, [3]Pauline Sambrook, [3]M. Sharratt, [3]E. Simchen, [3]C. J. Smart, [3 4 8]K. G. Smedstad, [3]D. N. Smith, [3]R. C. Stockdale, [3]R. L. Symonds, [3]T. F. T. T. K. Cheong, [3]Gertrude I. Terry, [3 8]R. W. P. Terry, [3]C. G. D. Thompson, [3]Elizabeth A. Treadwell, [3]D. P. Veerasamy, [3]E. Walker, [3]P. B. Welsh, [3]P. Y. Yeoh, [3]Anne B. Zachary.

Appointments.—Dr. M. G. Fitzgerald (part-time lecturer in medicine for dental students); Drs. F. Humphries and A. S. Ward (temporary lecturers, Department of Anatomy); Dr. T. Hollingworth (temporary lecturer, Department of Pathology).

[1] With honours. [2] Degree of Ch.B. with honours conferred *in absentia* by special warrant on 20 June 1967. [3] Degree of Ch.B. conferred *in absentia* by special warrant on 20 June 1967. [4] Distinction in medicine. [5] Distinction in obstetrics and gynaecology. [6] Distinction in pharmacology and therapeutics. [7] Distinction in surgery. [8] Distinction in pathology and bacteriology. [9] *In absentia.*

LIVERPOOL

Appointment.—Janine M. Miller, M.B., M.R.C.O.G. (lecturer in obstetrics and gynaecology).

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a meeting of the College held on 27 July licences to practise were conferred upon the following candidates who had passed the final examination in medicine, surgery, and midwifery of the Conjoint Board and had complied with the By-laws of the College:

C. K. Adrian, F. Afshar, P. J. Aggett, H. M. Agrama, J. K. Anderson, J. T. H. Anderson, D. Arrowsmith, C. C. Bailey, Q. R. Bailey, E. J. Barrington-Ward, A. M. Bateman, G. A. Battersby, M. J. Bendall, P. D. Black, J. C. Bolton, E. M. Bradbury, M. J. Britton, G. W. Brown, G. D. Budhlall, B. J. Burke, J. R. K. Butchey, E. W. M. Carrette, Susan Caton, M. G. T. Chapman, Elizabeth A. Charlesworth, N. M. Chitimba, W. R. L. Clemmey, D. F. Cochrane, R. G. Cockbain, Gillian M. Cockersole, P. J. Cole, A. J. Collyer, E. H. Compton, Catherine J. Crofton, C. W. Davies, E. P. Davis, M. H. Dober, G. O. Dunn, P. T. Edington, Judith M. Egerton, C. A. Ellison, B. T. Evans, C. W. Evans, M. Faruhar, R. H. Felix, D. P. Forster, A. P. Freeland, M. O. Freeth, R. S. Gale, R. H. L. Galliver, W. H. Goss, A. J. Hamilton, R. P. D. Hancock, P. Harker, R. Hart, A. R. Hayward, J. A. Hensel, Gillian I. Hodgkinson, Elizabeth A. Horder, G. L. Horner, Jane R. Howard, R. A. Hurlow, N. Irish, R. J. G. Irons, J. A. Isserlin, J. R. Jackson, J. D. James, I. M. Jaye, Sally A. Jobling, B. R. Jones, T. E. Jordan, R. K. Kolhatkar, Maureen E. Lawrence, T. R. Lee, P. J. Leopard, T. C. Leung, C. E. Lewis, M. J. Leyland, A. B. Loach, M. J. Lockwood, R. N. Lucas, A. H. Lynn, D. E. Macfarlane, G. P. C. McLaren, J. N. MacLean, Jennifer M. McMillan, W. D. McNicoll, Hilary J. Marcham, B. E. Mason, R. F. J. Matthews, R. S. Maurice-Williams, T. K. Meikleham, H. B. Meire, Margaret M. Miles, Susan C. Mitchell, R. J. C. Morris, H. M. T. Murphy, Rhinedd M. Peregrine-Jones, D. J. Peters, Susan A. Pettit, H. S. Phillips, Elizabeth R. Phipps, J. G. Pickering, Rita B. Rahman, A. D. Revel, J. C. Richardson, T. Rigby-Jones, R. C. G. Rowe, R. D. Rubens, T. J. Rudman, D. J. Seager, J. A. Seaman, M. E. Setchell, Lynn Sherlaw, R. B. Simonis, A. G. Simpson, Diana L. Smith, J. R. M. Smith, P. D. Snashall, B. Steer, M. J. Stevens, B. A. Stoner, D. Stratton, W. St. C. Symmers, D. R. Tant, R. E. Taor, J. F. Towers, C. Tranmer, C. F. Tredgold, Angela M. Trueman, I. M. Vickery, R. Warner, R. T. Watson, Caroline R. Weinberg, W. H. Weston-Davies, C. J. H. Williams, J. L. Williams, R. H. Williams, Janis A. Winter, Jean M. Worms, J. W. Wright, R. A. L. Young, Katherine H. Aplin

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting of the College held on 25 July, with the president, Dr. C. W. Clayson, in the chair, the following were elected Fellows of the College:

R. B. Mehta, J. G. Parekh, D. W. Burton, J. A. Morton, R. B. Baird, A. D. Muir, Sheila S. Paul (née Martin), Leila Ramakumar (née Nair), P. C. MacGillivray, S. G. F. Wilson, J. Hampson, B. Ll. C. Phillips, G. F. M. Russell, M. B. Azami, R. D. Montgomery, E. H. Mirando, R. Sougin-Mibashan, G. Arjundas, G. D. Forwell, Kee Jin Lim, Cheng Siang Seah, C. G. B. Downie, A. E. Hugh, A. D. Macdonald, R. G. Paley, L. G. Topham, R. D. Catterall, K. K. Gupta, Evelyn Hanam, Hau Cheong Kwaan, D. A. Seaton, I. W. Delamore, J. Syme, M. A. Z. M. Din, A. R. May, B. S. L. Kidd, M. A. A. Khan, S. O'Reilly, H. C. Jeffrey, F. S. Fiddes, F. M. Parsons, W. M. McCrae, W. L. MacD. Perry, T. N. Fraser, F. J. Gillingham.

The following were elected Members of the College:

A. S. Duncan, J. H. Tyrer, A. E. H. Emery, P. M. Ward, E. H. Wyatt, A. Razzaq, A. P. Brahman, A. Hamid, N. P. Misra, W. I. Lamont, H. G. Egdell, A. V. Barford, P. K. D. Gupta, P. F. Binnion, C. M. Tiwary, Joyce E. Richardson, L. M. Marinovich, P. J. C. Ashurst, A. R. Al Yusuf, W. E. Kirkpatrick, D. A. Rajapakse, M. M. Singh, A. Khaliq, V. P. Sachar, D. P. B. Goldberg, A. B. Kaplan, Isla M. Williams, N. N. Desai, M. A. Siddiqui, Urmila Bassi, S. K. Mondol, J. L. Waddell, A. T. Sinniah, A. D. Ginsburg, D. H. Kenward, M. M. Jaffe, N. B. S. Sarkari, B. Sharma, Sheila L. Waller, M. Black, A. R. M. Musa, G. K. Ahuja, M. Amare, A. I. Muir, N. Gitlin, B. Himpoo, S. M. Shrestha, E. J. W. Stephens, S. K. Kajubi, M. L. Oduori, B. Mason, A. G. Mowat, H. C. Mulholland, Jean S. Thomson, Mo-Wah Chan, Moinuddin, Lai Chan See, Rosemary H. Marshall, C. C. Smith, G. O. Cowan, R. H. Macdonald, J. E. Ogwo, A. H. de C. Freed, Yat Tung Wong, A. G. Knight, R. B. L. Ewart, N. D. C. Finlayson, M. R. Higgins, I. M. Murray-Lyon, T. J. Peters.

A Hill Pattison-Struthers bursary has been awarded to Dr. Ijaz Haider.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At a meeting of the College held on 7 July the following were admitted *in absentia* to the Fellowship:

S. Lourdenadin, E. D. U. Powell.

G. H. Cussen was admitted to the Licence and Membership of the College.

Deaths

Stanford.—On 14 July 1967, at King Edward VII Hospital, Midhurst, Sussex, Russell Aubrey John Stanford, M.B., B.Ch., B.A.O., of Scunthorpe, Lincs, aged 58.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON W.C.1. TELEPHONE: 01-387 4499. TELEGRAMS: *Aitiology, London W.C.1.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs.

ADVERTISEMENT AND SUBSCRIPTION ORDERS should be addressed to The Manager at B.M.A. House, London, or at 415 Bourke Street, Melbourne, Victoria, Australia.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the British Medical Association, B.M.A. House, London, or to the Scottish Secretary, B.M.A. Scottish Office, Drumsheugh Gardens, Edinburgh.

Acute Tubular Necrosis: Follow-up studies by Dr. J. D. Briggs and colleagues revealed that 75% of patients had reduced glomerular filtration rate, but were clinically well up to three years after acute renal failure (p. 513).

Bradford Maternity Experiment: The discharge of mothers from hospital 72 hours after delivery resulted in no greater mortality or morbidity of their babies compared with those born at home, according to Drs. M. W. Arthurton and F. N. Bamford (p. 517). Mr. G. A. Craig and Dr. J. M. B. Muirhead consider the early discharge scheme has not increased maternal morbidity but enabled the maximum number of patients to have the benefit of hospital care (p. 520). Leader at p. 508.

Prognosis in Breast Cancer: Mr. B. S. Thomas and his colleagues confirm the usefulness of a simple ratio of total urinary 11-deoxy-17-oxosteroids to the 17-OHCS in predicting response to endocrine ablation (p. 523).

Mental Function in the Aged: Dr. J. A. C. Ball and Mr. A. R. Taylor found that cyclandelate appeared to improve mental function, probably owing to redistribution rather than increase of blood flow (p. 525).

Tic Douloureux: Review of 10 patients with glossopharyngeal and vagal neuralgia satisfactorily treated by intracranial nerve root section by Mr. Jagdish C. Chawla and Mr. Murray A. Falconer (p. 529).

Foetal Haemoglobin Variant: Dr. L. S. Sacker and colleagues found this in two unrelated families in Hull (p. 531)

Complication of Thyroid Cancer: Nine cases of paraplegia due to spinal metastases described by Dr. K. E. Halnan and Mr. P. H. Roberts (p. 534).

Case Reports: Babies with hypernatraemic dehydration from improper feeding (p. 536). Anaemia in scleroderma (p. 537).

Should the Patient Fly?: Dr. K. G. Bergin outlines contraindications, restrictions, precautions, and facilities available (p. 539).

Hypertension, Anuria, and Uraemia: Clinicopathological Conference at Royal Postgraduate Medical School (p. 544).

Speech in Respiratory Failure: Dr. R. M. L. Whitlock describes attachment to cuffed tracheostomy tube (p. 547).

Medicine in Burma: Professor A. W. Woodruff describes remarkable progress in the absence of extensive foreign aid (p. 551).

Banned Doctor: Letter about Dr. Raymond Hoffenberg (p. 556). Leader at p. 512.

Public Health Service Dispute: "Useful discussion" (*Supplement*, p. 124).

Rise in Industrial Accidents

The latest pair of annual reports from the Chief Inspector of Factories[1,2] show once again that serious accidents are far too common and that much more needs to be done to protect the health and safety of people at work. The number of reported accidents in Great Britain (entailing at least three days' absence from work) again rose in 1966 over the previous year's total. The actual number of 296,610 cannot provide any certain measure of whether the accident rate as such went up or down, partly because the numbers of people exposed to risk are not precisely known, and partly because the extent to which reportable accidents are in fact being reported may be improving. But what is specially worrying is the considerable rise in the number of fatal accidents—from 627 in 1965 to 701 in 1966. An increase of 12% in one year needs serious attention, especially since the general trend since 1948 had for some years been downwards.

Part of the present trouble is due to a continual increase in the exposure of men and women to the risk of accidental injury. New industrial processes are being introduced every year. With them come machines with unsuspected dangers as well as substances with scarcely known toxic hazards. The new technology of which all this forms a part is undoubtedly something with which man must come to terms. But it seems to be too often forgotten that the inventive talents engaged on increasing production should also be used to increase the safety of the new processes. The Factory Acts and the inspectorate can provide no more than the framework within which safe practices must ever be taught, encouraged, and insisted upon at every industrial site. The Chief Inspector emphasizes, as he has before, that top management in a firm must "plan for safety just as they plan for production." And to the planning must be added an impetus from the top to see that the procedures are safely carried out: "The first prerequisite of accident prevention is a safety consciousness on the part of all people working in the factory—from the Managing Director down to the lowest operative." These principles are apt to be neglected more in the small firms than the large. Almost invariably, it is reported, no particular person is made responsible for safety in such careless firms until a serious accident occurs.

That young people in industry are bound to present a special problem should need no emphasis, yet the Chief Inspector has to draw attention once again to the high accident rate among them. Partially trained, inexperienced, and with the natural impetuosity or even recklessness of their years, young people need more supervision than they are receiving among the hazards of working machinery. To deny it to them shows, in the words of the report, "a wanton disregard of moral responsibility," and it lays blame for most of the accidents to the young on the managers, supervisors, or foremen. These experienced people in authority too often fail to give sound guidance or set a good example. Probably the majority of the young people starting life on the factory floor are below the national average in intelligence owing to the opportunities for the cleverer ones to

© *British Medical Journal*, 1967. All reproduction rights reserved.

find work elsewhere, so that a particular obligation to care for their safety must be acknowledged. Nor is the transition from school to industry a smooth passage for some people,[3] coming for many at a time of rapid physiological and psychological development.

When he comes to report on industrial health[2] the Chief Inspector has a story with a happier ending—"With the exception of the lung dust diseases, the grosser forms of industrial poisoning have been virtually eliminated." Cheap to make, expensive to suppress, a multitude of dusts pervade the industrial environment, and a special section of the report by Mr. B. H. Harvey and Dr. W. D. Buchanan is devoted to them. Though initially they present a problem for each individual industry to solve, their effects closely concern the medical men who care for the workers in it, and for them some of the details in the present report will be of interest.

Despite improvement over the years in the industrial environment these reports show clearly that much remains to be done. Moreover, the quality of safety provisions varies enormously throughout the country—from the excellent to the deplorable. No comprehensive industrial health service has yet been set up, though often advocated by the British Medical Association.[4-8] From the latest reports it is evident that the need is still there. Indeed, the practice of many large firms with their own medical staff has abundantly demonstrated the benefits of thorough medical supervision in industry. There should be some way of bringing these benefits to the smaller firms, which, between them, employ the majority of workpeople.

Early Discharge of Maternity Patients

It is now some three years since the advantages and disadvantages of the early discharge of maternity patients were discussed in these columns,[1] and in view of the increasing support for the idea since then the two further reports in the *B.M.J.* this week are timely. Both of them are from Bradford—one by obstetricians and the other by paediatricians—and they present an impressive number of cases, for the regimen has now been in use there since 1956 and some 13,000 puerperal patients have been managed in this way. Mr. G. A. Craig and Mr. J. M. B. Muirhead report (page 520) that in their experience planned early discharge does not result in increased maternal morbidity nor does it add to the risks of birth. Discussing the effects on the babies, Drs. M. W. Arthurton and F. N. Bamford report (page 517) that the regimen has had no serious adverse effect and may have contributed to an improvement in child health. But they go on to say: "There is no evidence that early discharge offers any advantage for the individual baby as compared with staying in hospital for ten days, and in fact there are additional risks partly attributable to difficulties in neonatal diagnosis." That the general practitioners welcome and actively support the Bradford scheme can be seen by the report of a survey of 100 cases of early discharge carried out by members of the Bradford Group of the College of General Practitioners.[2]

The latest results are of great interest. Statistically there appears to be no difference between the number of patients readmitted after planned early discharge and those admitted as an emergency after domiciliary confinement. Likewise, the perinatal mortality is the same in the two groups.

The length of time a patient remains in hospital after delivery depends on many factors. While the present shortage of maternity beds undoubtedly plays a large part, to this must be added the rules of the Central Midwives Board—a subject on which Professor P. Rhodes has recently written forcefully.[3] Another factor affecting the situation is the view of the patient herself, and it is the experience of many practising obstetricians that puerperal mothers are asking to be allowed home at an increasingly early date after delivery. The doubts about the dangers to mother and baby from early discharge are largely dispelled by the Bradford reports. However, there is a considerable difference between a scheme of this nature working at a high level of efficiency, as at Bradford, and occasional early discharge of a patient without the complete arrangements that the existence of such a scheme implies.

The patients ideally suited for early discharge are those multiparae whose past history necessitates hospital delivery for fear of a possible recurrence of their previous complication. To this main group might be added those normal multiparae who are apprehensive about home confinements. The selection of these cases can be largely done in the antenatal period. And, though the final decision is not made in the Bradford scheme until after delivery, it would seem advisable that, whenever possible, the mother should be informed of this probability early in pregnancy so that she can make the necessary arrangements for additional help at home in good time.

The success and safety of early discharge depend on close liaison between hospital, district midwife, and general practitioner. It is essential for the hospital to notify both of them by telephone on the same day as the patient is discharged, giving such information as may be needed. The district midwife is an essential part of the scheme; indeed, without her active support it will not succeed. In future it may be found helpful for arrangements to be made to allow either the domiciliary midwife to come into hospital to deliver her patients or the hospital midwife to undertake the home visiting of them after discharge.

[6] *The Planning of Early Discharge Schemes for Maternity Patients.* H.M.S.O. (65), 32.

From the Bradford reports it can be seen that the final decision to permit a mother and baby home after 48 hours must be made by someone at least of registrar status. It would also be of considerable value if the general practitioner and district midwife in charge of such a case could freely obtain an opinion by domiciliary consultation from either the hospital obstetric or paediatric department on any puerperal or neonatal complication before readmission of the woman after she has returned home.

When early discharge was discussed in these columns three years ago[1] the conclusion was drawn that, though it might be suitable in emergency conditions, it had little part in long-term planning. That reflected an opinion then prevalent and previously advanced by the Royal College of Obstetricians and Gynaecologists.[4] But it may well need revision. G. D. Pinker and A. C. Fraser[5] reported after a trial over three years at St. Mary's Hospital that the scheme was " safe and desirable " for both mother and baby and recommended that the voluntary early discharge of selected patients should be an accepted part of the maternity services. Advice on the planning of arrangements has been given by the Ministry of Health.[6] Now the two reports from Bradford indicate that it would be reasonable to explore the whole question further.

Activation Analysis

Radioactive isotopes have contributed to many advances in clinical science, especially during the last 20 years, when ample supplies have been available as by-products of the atomic energy programme. The complementary technique of activation analysis offers some distinctive advantages which deserve closer study.

The basis of this technique is that most elements are partially converted to radioactive isotopes on exposure to neutrons—for example, inside a nuclear reactor. The induced radioactivity is highly specific for the elements contributing to it. It is therefore possible to identify and estimate many of the elements present in a sample by studying the radioactivity induced by a short spell inside a nuclear reactor. This apparently roundabout procedure is, for many elements, the most sensitive method of analysis now available. Recently the use of this technique in the identification of human hair was discussed in these columns.[1]

The uses of activation analysis in clinical science are more often commended than practised, but useful progress was reviewed and discussed at the symposium on Nuclear Activation Techniques in the Life Sciences held in Amsterdam from 8 to 12 May under the auspices of the International Atomic Energy Agency. Several research projects are at present concerned with the elemental analysis of various body constituents in the hope of correlating pathological signs with abnormalities in the metabolism of minor elements not normally within the purview of the biochemist.

A typical inquiry entailed the estimation of seven trace elements in blood from normal persons and from patients with chronic uraemia. Levels of arsenic in the blood were on average three times higher in the uraemic patients. A suggestion that the apparent retention of arsenic may contribute to toxic manifestations of uraemia can hardly be supported, partly because the quantities are so small (about 5 μg. of arsenic per litre of blood) and also because no correlation has been found between arsenic level in the blood and degree of renal insufficiency as indicated by blood creatinine measurements. But speculative inquiries of this kind are worth while because they may sometimes provide the first clue to the solution of an intractable problem. Information of a more immediately useful kind can be expected from using activation analysis in problems where the underlying biochemical and physiological considerations are better understood.

Thyroid metabolism, much studied by radioactive isotopes, offers interesting problems for attack by activation analysis. Semi-automatic methods for the routine determination of protein-bound stable iodine have been elaborated, notably in France,[2] where the establishment of a laboratory to carry out such tests on a commercial basis is now being considered. The basis of the estimation is the partial conversion, under bombardment by thermal neutrons, of stable iodine-127 to the radioactive isotope iodine-128, which has a half-life of 25 minutes. Chemical manipulation is necessary to remove radioactive isotopes of sodium and other elements formed in abundance along with the iodine-128.

New prospects have resulted from the development (also in France) of techniques using iodine-129. This isotope has a very long half-life (1.6×10^7 years) and a number of other properties particularly useful for clinical applications. The gamma-radiation which it emits is of very low energy and gives a correspondingly small radiation dose to the patient, but can be detected in the thyroid gland by an external scintillation counter. It would be possible, by daily administration of small doses of iodine-129 to a patient, to attain isotopic equilibrium. When this state has been reached, the ratio of the concentration of iodine-129 to iodine-127 is the same throughout the body. Isotopic equilibrium cannot be reached with iodine-125 or iodine-131 because of the heavy dose of radiation which the patient would incur. With iodine-129 the total dose over a period of a year in isotopic equilibrium would be very much less than that incurred in a single tracer test with iodine-131, but the amount of information to be obtained by radioactive assay of blood, urine, and the thyroid itself would be substantially greater. The usefulness of this isotope is further enhanced by the fact that, on exposure to irradiation by thermal neutrons, it is partly converted to another radioactive isotope, iodine-130 (and its isomeric form, iodine-130m) allowing detection at excellent sensitivity by activation analysis.

The technique of activation analysis in vivo, first reported on by J. Anderson and others[3] in 1964, offers the possibility of direct measurement of the total stable iodine content of the thyroid. In principle, the stable iodine-127 in the thyroid can be activated by neutron bombardment to yield radioactive iodine-128, which can be measured by external counting. In practice this simple technique cannot give accurate results, mainly because of the impossibility of achieving uniform irradiation of the thyroid gland by neutrons. A technique entailing prior administration of iodine-129, followed by neutron irradiation of the thyroid and simultaneous estimation (by external scintillation counting) of iodine-128, 130, and 130m, provides an accurate estimate of thyroid iodine in the sheep and may soon be applicable to man.[4]

The remarkable sensitivity of activation analysis has been exploited in studies of the electrolyte equilibrium of the fluids of the inner ear. The dynamic equilibrium between perilymph (which is a fluid of the extracellular type, with sodium predominating over potassium) and endolymph (in which potassium ions greatly outnumber sodium ions) is linked with the functions of hearing and balance. Reliable estimates of the concentrations of sodium and potassium have been obtained by activation analysis of small samples of fluid (2–10 μl.) obtained from experimental animals, and there are grounds for hoping that this technique also may be extended before long to man.

Architectural Aids for Disabled

One of the shocks a patient commonly experiences on becoming severely disabled is to find how many activities that he formerly took for granted are now beyond his reach. Many disabled people adjust to restrictions on movement and activities by developing new skills, by using ingenuity to surmount obstacles, and so by sheer determination contrive to manage for themselves in an unsympathetic environment. Part of their adjustment lies in appreciating the things they cannot do. Rather than be frustrated in the attempt, they learn to leave them alone. Some retire into their disability and do less and less. Thus instead of trying to get up the imposing flight of steps that leads to the public library or cinema, up which normal folk skip so blithely, they prefer not to use the library or cinema at all.

In recent years architects have given more thought than formerly to the special physical characteristics of the people who will use the buildings they are designing. Schools were the first to be thought of in this way[1] and then to some extent hospitals. The Ministry of Housing published a design bulletin[2] in 1962 drawing attention to features and dimensions desirable to incorporate in flatlets built for old people so as to meet their physical limitations, the recommendations being based on investigations carried out by Ministry sociologists[3] and an anthropometric study.[4] But the special requirements of the disabled received little attention until the Royal Institute of British Architects' publication of 1963.[5] Now the British Standards Institution commendably publishes a new code of practice, C.P. 96: Part I. Access for the Disabled to Buildings. It details the architectural provisions which should be incorporated in new buildings to make them convenient for disabled and infirm people to use. It is the product of a committee in which many groups with special knowledge of the needs and capabilities of the disabled, such as the British Council for Rehabilitation of the Disabled, the Central Council for the Disabled, the Spastics Society, and the British Medical Association, shared that knowledge with representatives of the interested professional bodies, including the Royal Institute of British Architects, the Royal Institution of Chartered Surveyors, and various Government departments.

The new code covers ambulant-disabled people and the wheelchair-bound especially, but also incorporates a short section on the special requirements of the blind and the deaf. It is based both on empirical observation and on specific pieces of research—for example, into suitability of different designs of door handles,[6] into the manœuvring space of wheelchairs, and into the layout of sanitary and cloakroom accommodation. Many of these studies were sponsored by the bodies represented on the committee. The recommendations are such as can be carried out, for they are realistic rather than idealistic and economic considerations have been taken fully into account, as indeed they must be when any public building is planned. The new code of practice follows the lead of the American[7] and Canadian[8] standards, though it departs from the former in one significant feature in stressing the need for the signposting of special facilities for disabled people.

Nobody knows how many disabled there are in Britain. The American[7] and Canadian[8] recommendations take the figure of one in seven of the population as having a permanent physical disability or an infirmity associated with age. A survey carried out in Denmark[9] in 1961–2, based on one person in 140 of the total population, identified 6.5% of persons aged 15 to 61 as physically handicapped. Many of these are not so disabled as to need special facilities, but information from various sources, such as the number of wheelchairs issued by the Ministry of Health, suggests that even if a similar proportion is not applicable to the British population the total here runs into hundreds of thousands. The new code of practice, wherever implemented, will mean that these hundreds of thousands will have freer access to shops and stores and churches and libraries and cinemas and hotels than they have hitherto had and so will be able to take part more easily and more fully in everyday activities.

Allergic Gastroenteropathy

The combination of oedema of obscure origin, hypoalbuminaemia, and gastrointestinal disturbance suggests the possibility of exudative enteropathy or protein-losing gastroenteropathy. This syndrome may be associated with giant hypertrophy of the gastric rugae,[1] regional ileitis and ulcerative colitis,[2] sprue,[3] intestinal lipodystrophy,[4] gastric carcinoma,[5] intestinal lymphangiectasia,[6] constrictive pericarditis and congenital atrial septal defect,[7] neonatal steatorrhea with small-bowel dysfunction,[8] and hypogammaglobulinaemia.[9] To this growing list of causes of protein-losing gastroenteropathy may now be added a group of six young children with oedema, extreme hypoproteinaemia, anaemia, eosinophilia, and retardation of growth.[10] This new syndrome has been delineated on the basis of clinical features, gastrointestinal radiography, intestinal biopsies, and favourable response to corticosteroid therapy. The last distinguishes it in this age group particularly from intestinal lymphangiectasia, coeliac disease, and hypogammaglobulinaemia. T. A. Waldman and colleagues[10] propose the term allergic gastroenteropathy to delineate their series of cases because milk aggravated the protein-losing gastroenteropathy. Precipitating antibodies to milk were detected in the serum of three patients. The patients improved on a milk-free diet and relapsed when milk was reintroduced. The favourable response to the administration of corticosteroids, together with clinical signs of asthma, eczema, and rhinitis, all contributed to the concept of an allergic gastroenteropathy.

This series of six children comprised four boys and two girls. The age at onset of oedema was under 3 years in all but one child. Oedema was most marked in the periorbital area. Gastrointestinal symptoms included diarrhoea and vomiting after milk; but lactose tolerance tests were normal. Gastrointestinal *x*-ray examinations showed mucosal oedema of the small bowel in four and puddling and segmentation of barium in one patient. The authors are confident that this distinctive syndrome is not attributable to any of the previously recognized conditions that give rise to excessive loss of protein into the gastrointestinal tract, and that a trial of treatment with a milk-free diet or with corticosteroids is worth while.

Hitherto the clinical patterns of disease associated with loss of protein have been classified according to whether the lesion is outside or inside the gastrointestinal tract: in the heart, liver, or pancreas, or in the stomach, small intestine, or the colon. We must now also keep in mind gastrointestinal allergens, whether food or drug, which may contribute in turn to this gastrointestinal upset, metabolic disorder, and systemic disease, for early recognition is the first step away from the label "idiopathic oedema" and towards a rational basis of treatment.

Correction of protein-losing gastroenteropathy has followed surgical treatment of constrictive pericarditis and other cardiac abnormalities.[7] Gastrectomy for giant hypertrophy of the gastric rugáe has effected a cure, and so has putting gluten-allergic patients on a gluten-free diet. Corticosteroid therapy has proved beneficial in ulcerative colitis, and now also for milk-allergy protein-losing gastroenteropathy.

Oxygen Therapy Equipment

Oxygen is usually given in low dosage (25% to 40%) for treatment of hypoxaemia due to uneven lung function. In particular it may be given for under-ventilation or over-perfusion of groups of alveoli. The patient is usually suffering from lung disease[1] or has a disturbance of the pulmonary circulation, as in some cases of myocardial infarction.[2] Oxygen is given in high dosage (70% to 100%) both to produce a high tension in the blood, as for treatment of carbon monoxide poisoning, and to increase the quantity of oxygen carried in solution in blood plasma. The latter procedure may contribute to the relief of tissue hypoxia due to ischaemia and of hypoxaemia due to blood by-passing ventilated regions of lung. Both these conditions arise in patients with severe myocardial infarction.[3]

A high dosage of oxygen in a patient whose breathing is not depressed may be secured with a half face mask which makes a good fit on to the face and is supplied with a generous flow of oxygen (6–10 l./min.). The effectiveness of the oxygen is enhanced by using a mask with a reservoir bag for conserving the gas which would otherwise flow to waste during expiration—for example, the Portogen mask. Use of a mask which falls from the face on interruption of the oxygen supply—for example, the Pneumask—has some advantage, but is not essential, because with adequate respiration the interruption is unlikely to give rise to asphyxia. If breathing may become depressed a more positive means of administration is desirable.

Oxygen in low dosage is easily provided and does not require a perfectly fitting mask. As only a low flow is required there is no need for conservation of oxygen during expiration except when portable equipment is used. The risk of asphyxia is small for patients who are hyperventilating—for example, those with a defect of gas transfer in the lungs or in a state of shock. But this type of therapy is usually needed for patients whose ventilation is low, perhaps owing to an acute chest illness superimposed on chronic lung disease or to depression of the respiratory centre. Here the oxygen should relieve the hypoxaemia sufficiently to prevent tissue damage, but preferably without eliminating the hypoxic drive to respiration. An arterial oxygen saturation of 90% is suitable for this purpose. The gas should be administered in controlled dosage and, when appropriate, with monitoring of the blood carbon-dioxide tension and *p*H. This is to prevent hypoventilation leading to carbon dioxide narcosis owing to reduction of the stimulus to breathing. For these patients the device should have minimal dead-space to avoid aggravation of the carbon dioxide retention. The dead-spaces of equipment in current use have recently been investigated.[4]

Plastic nasal catheters meet the requirement, are comfortable, and can be used during meals, but the oxygen then requires humidification, and for a few patients mouth breathing may lower the effective dose. The Ventimask is also satisfactory and has the advantage that the concentration of oxygen is nearly constant.[5] However, up to three face pieces may be needed per patient if a range of concentrations is required (24%–35%). Of the others which do not conserve oxygen during expiration, the M.C. mask was found to have a significant dead-space[6] and so to be inferior to the Edinburgh mask, in which there is free communication with the outside air.[7] The latter mask is probably the best single one for general use.

Masks which have a large dead-space include the Polymask, Pneumask, and those of the B.L.B. type. Because of the hazard of rebreathing these should never be used for patients who are liable to carbon dioxide narcosis. In addition, while the masks can provide high enrichment of oxygen for patients needing 100% oxygen, they are inferior in this respect to masks like the Portogen, mentioned above, in which rebreathing is prevented by use of valves.[8]

Modern oxygen therapy requires separate devices for administering oxygen in high and low doses. The physician is now in a position to select the most suitable one for each purpose from the equipment commercially available.

Children in Care

Until about 1960 the annual numbers of illegitimate births and of marriages ending in divorce in England and Wales had not shown a distinct trend up or down since the peak years immediately after the second world war. Then in 1961 the rates for both rose sharply, and they have continued to do so. In 1965[1] the number of illegitimate babies born was 66,249, or 77 per 1,000 total live births, and the number of divorces was 37,785, or 3.1 per 1,000 married population. Since in many cases the welfare of young children is affected, it is no surprise to learn from the latest report of the Children's Department of the Home Office[2] that between 1959 and 1966 the total number of children in the care of local authorities and voluntary organizations in England and Wales rose from 78,648 to 79,995 But some comfort may be taken from the fact that the increase was not greater, for it actually represents a fall from 6.5 to 6 1 per 1,000 of the population aged under 18.

Illness of a parent and confinement of the mother together provide the main immediate cause of children coming into the care of local authorities; the second largest cause of being taken into care is desertion by the mother. The increase in the latter type of cases from 1963 to 1966 was 31%. More remarkable perhaps is the increase of 81% (from 1,319 to 2,283) in the same period of children taken into the care of local authorities owing to unsatisfactory home conditions. The continual improvement in housing for some years might have suggested that a diminution in this category would have been more probable than such a substantial increase.

Since it is now generally acknowledged that a child is better brought up in a family than in an institutional home, however kindly and carefully run, it is worth noting that children's departments are placing many more children with foster parents than formerly and that the numbers of legal adoptions continue to rise each year. Between 1959 and 1965 the number of children adopted annually rose by 50% from 14,000 to 21,000. Of the latter total 80% were illegitimate. In view of the important contribution that adoption is now making to the well-being of a considerable fraction of the population the special problems it poses deserve careful study. This is equally true of the individual case, in which a medical man may be called upon to give an opinion in a variety of circumstances. The pitfalls in trying to assess the future health of very young babies are well known, and they are more numerous than usual when one or both parents are inaccessible, as is a feature of many adoption cases. Some of the special problems have been discussed by J. A. Black and F. H. Stone.[3] But a doctor's role may extend far beyond an assessment of the child's health and thrust upon him legal as well as medical responsibilities. Of these Hilda Lewis[4] provided an instructive account.

As the report says, "Far too little is known about what makes for a successful adoption, or indeed about how one should measure 'success.'" It might perhaps have said the same of parenthood. However that may be, society must accept a special responsibility to ensure that the adoptive procedures it sanctions are as beneficial as possible. Consequently, the studies of its efficacy sponsored by the Home Office, and briefly mentioned in the report, are to be welcomed.

Sentence Without Trial

A letter in our correspondence columns (p. 556) draws attention to the case of Dr. Raymond Hoffenberg, senior lecturer in the Department of Medicine at Cape Town University, on whom the South African Department of Justice has recently served a banning order. Professor John F. Brock, head of the department in which Dr. Hoffenberg works and President of the College of Physicians, Surgeons, and Gynaecologists of South Africa, has already strongly condemned the action of the Department of Justice.[1]

Dr. Hoffenberg is a distinguished physician, medical scientist, and teacher at Groote Schuur Hospital, Cape Town, known and consulted internationally for his work on radioisotopes, thyroid function, and protein malnutrition. He was formerly acting chairman of the banned South African Defence and Aid Fund, a body which helped political prisoners.[2] Two years ago his passport was withdrawn. No charges were made against him, and inquiries by Professor Brock failed to elicit the reason for the withdrawal. Nor recently could he obtain permission for Dr. Hoffenberg to attend, on behalf of his hospital and university, an international atomic energy meeting in Vienna to which he had been invited. Now a five-year banning order has been imposed, again without any charges being made. The ban[3] restricts Dr. Hoffenberg to the Cape Town area, requires him to report weekly to the police, and prevents him from attending any gathering, social or otherwise, of more than one person. He is forbidden to publish, and this apparently includes scientific articles. He must give up his academic appointment at Groote Schuur Hospital at the end of this year. In the words of correspondents to *The Times*,[4] "He is removed from the world of medical science, to which he has made notable contributions; he is expunged from society"—all without trial.

Banning orders have been applied to other citizens of South Africa, but not before, it seems, to a medical man. Many South African doctors are shocked by what has occurred, and the College of Physicians, Surgeons, and Gynaecologists, the South African Medical and Dental Council, and the Medical Association of South Africa are to be asked to report on Dr. Hoffenberg's case.

By its actions the Department of Justice has effectively deprived the world of medicine, abroad as well as in South Africa, of the services of a distinguished doctor. No research worker can hope to maintain his impetus without freedom to associate with colleagues, to travel, and to publish his findings. It concerns the profession everywhere that any State, without charge or trial, should thus excommunicate a doctor from his professional life. South Africa will damage only its own reputation if it persists in penalizing Dr. Hoffenberg without a fair hearing.

Papers and Originals

Renal Function after Acute Tubular Necrosis

J. D. BRIGGS,* M.B., M.R.C.P., M.R.C.P.ED., M.R.C.P.GLASG.; A. C. KENNEDY,† M.D., F.R.C.P.ED., F.R.C.P.GLASG.
L. N. YOUNG,‡ M.B., M.R.A.C.P.; R. G. LUKE,§ M.B., M.R.C.P., M.R.C.P.ED.
MARY GRAY,‖ B.SC.

Brit. med. J., 1967, 3, 513–516

As a result of a revision in the conservative methods of treatment (Bull *et al.*, 1949) and the availability of haemodialysis and peritoneal dialysis survival can now be expected in a substantial proportion of patients with acute tubular necrosis (Teschan *et al.*, 1960; Kennedy *et al.*, 1963). In the fatal cases death is usually due to the initiating illness, overwhelming infection, or a complication of uraemia such as uncontrolled hyperkalaemia or haemorrhage, and rarely to irreversibility of the renal lesion.

Recently the accuracy of the term "acute tubular necrosis" has been challenged (Sevitt, 1959; Finckh *et al.*, 1962) and alternatives such as acute reversible intrinsic renal failure have been suggested (Luke and Kennedy, 1967). However, in view of the common usage and widespread understanding of the meaning of the term acute tubular necrosis, it will be used in this paper.

Although it is widely accepted that the prognosis in general is good in patients who survive an episode of acute tubular necrosis, there remains some doubt about the exact degree to which glomerular and tubular function will ultimately recover. Lowe (1952), in a preliminary report, found in 14 patients followed for periods varying from 7 to 38 months that renal function tests tended to remain below normal limits, and these findings were largely confirmed by Finkenstaedt and Merrill (1956) in 16 patients followed for 3 to 76 months, though their patients had normal tubular function in spite of a diminished glomerular filtration rate. Edwards (1959), however, reported a return to normal of the rate in 14 out of 15 patients within three months.

The present paper describes the degree of recovery of various aspects of renal function after acute tubular necrosis in 50 patients studied on average at 35 months after the episode of renal failure.

Methods and Material

Fifty patients were studied, 22 male and 28 female, all of whom had a previous well-documented episode of acute tubular necrosis. A total of 138 patients with acute tubular necrosis were admitted to the artificial kidney unit of Glasgow Royal Infirmary during the period February 1960 to June 1965, and the 50 patients in the present study were selected from the 88 survivors. The only method of selection was on the grounds of availability and knowledge of their whereabouts: there is no reason to suspect that these do not form a representative sample of the patients recovering during this period. The ages of the patients at the time of development of the acute tubular necrosis ranged from 18 to 67 years, with a mean of 38 years. The diagnosis of acute tubular necrosis was made on the grounds of the clinical presentation, course of the illness (Loughbridge *et al.*, 1960), and biochemical investigations: the ratio of urine urea to blood urea fell at some stage in the illness to less than 4:1 in all patients.

The aetiology of the acute tubular necrosis is shown in Table I. The patients were subdivided in the conventional manner into medical, surgical, and obstetric groups. The commonest precipitating factors were abortion, antepartum haemorrhage, surgery, multiple injuries, and ingestion of nephrotoxins, these together accounting for 68% of the entire series.

TABLE I.—*Aetiology of the Acute Tubular Necrosis*

Medical (12)	Surgical (17)	Obstetric (21)
Nephrotoxins (4)	Postoperative (7)	Abortion (11)
Intravascular haemolysis (2)	Multiple injuries (5)	Antepartum haemorrhage (7)*
Pneumonia	Cholecystitis (2)	Postpartum haemorrhage (3)*
Anticoagulant bleeding	Burns + intravascular haemolysis	
Salmonella enteritis	Intestinal obstruction	
Carbon monoxide poisoning	Perforated duodenal ulcer	
Respiratory failure		
Staphylococcal septicaemia		

* Following pre-eclampsia in 9 out of 10 cases.
Number of patients in each group shown in parentheses.

All grades of severity of renal failure were encountered. This was assessed in two ways—by the duration of oliguria (urine volume of less than 600 ml. per 24 hours) and by the number of dialyses performed. Forty-four of the 50 patients were oliguric for periods ranging from 2 to 40 days, with a mean of 11 days; one patient was not oliguric at any stage of the illness; and in the remaining five patients the duration of oliguria was not known. Haemodialysis was required on at least one occasion in 43 patients. The greatest number of dialyses in any one patient was 15: this patient had a severe degree of renal failure after multiple injuries and was oliguric for 40 days. In the remaining seven patients conservative measures only were used.

Evidence of previous urinary tract disease was present in six patients. Three gave a history of recurrent urinary tract infection, two had symptoms suggestive of prostatic enlargement, and one was a mild maturity-onset diabetic, in whose urine a trace of protein had been noted on several occasions. In addition three patients had significant hypertension (diastolic blood pressure of 100 mm. Hg or higher) and nine had pre-eclampsia at the time of onset of the acute tubular necrosis.

The interval between the episode of acute tubular necrosis and the follow-up study varied from 4 to 75 months, with a mean and standard deviation of 35±19 months, but in only two patients was it less than one year. A less detailed interim follow-up study was also carried out in 14 of the 50 patients. The mean interval between the acute tubular necrosis and the interim study was nine months and between the interim and formal follow-up studies 37 months.

The formal follow-up study consisted of a clinical assessment plus the following investigations: quantitative urine microscopy and culture (McGeachie and Kennedy, 1963), estimation of proteinuria with the biuret method, blood urea and electrolytes, serum creatinine, and measurement of glomerular filtration rate, concentrating power of the kidney, and ability to excrete an acid load. The glomerular filtration rate was estimated by three methods—endogenous creatinine clearance (49 patients), inulin clearance (41 patients), and the clearance of ^{57}Co-labelled vitamin B$_{12}$ (Nelp *et al.*, 1964) (41 patients). Only the results of the inulin and endogenous creatinine clearances are presented here, as the ^{57}Co-labelled vitamin B$_{12}$ clearance was in fairly close agreement with the inulin clearance (Briggs, 1967). Concentrating power was assessed by measurement of urine specific gravity after 24 hours' dehydration and the ability of the kidney to excrete an acid load by the modified acid load test of Wrong and Davies (1959). In the interim follow-up the following studies were made: urine culture, estimation of proteinuria, blood urea, endogenous creatinine clearance, and pitressin test.

Results

At the time of follow-up all the patients were leading active lives and almost all had returned to their former occupation. Few symptoms which had a possible relation with the acute tubular necrosis were elicited. Three patients complained of excessive tiredness, in two of whom the glomerular filtration rate was moderately reduced. Nocturia was present in nine patients but was as common in those with a normal glomerular filtration rate as in those with a reduced rate. Four of the 17 married women under 40 years had one or more successful pregnancies after the acute tubular necrosis.

Blood pressure.—This was measured a few hours after the patient's admission to hospital while resting in bed. In 36 of the 50 patients the diastolic blood pressure was 90 mm. Hg or less. Eight patients had values between 91 and 100 mm. Hg, while in the remaining six the diastolic blood pressure was greater than 100 mm. Hg. Of this last group, two were known to have had hypertension before the acute tubular necrosis, while the remaining four had pre-eclampsia. Three of the eight patients with levels of 91–100 mm. Hg also had pre-eclampsia and one pre-existing hypertension.

Proteinuria and Urine Microscopy.—The urine was protein-free in 34 patients, and in a further 10 less than 1 g. of protein per 24 hours was recorded. The remaining six had 1 to 3 g. of protein per 24 hours: of these, three had pre-eclampsia before the acute tubular necrosis, one had recurrent pyelonephritis, and one had hypertension with impaired renal function. Urine microscopy revealed pyuria in seven patients, four of whom also had significant bacteriuria.

Urinary Infection.—Significant bacteriuria—that is, more than 100,000 organisms per ml. of urine—was present at the time of follow-up in six patients. This compared with the finding of bacteriuria at some stage of the acute tubular necrosis in 23 patients. Of the six patients with positive urine cultures at follow-up, two gave a history of recurrent urinary tract infection extending back beyond the acute tubular necrosis, one had radiological evidence of pyelonephritis with impaired renal function and was thought in retrospect to have long-standing, occult, chronic pyelonephritis, one had previous pre-eclampsia but no urinary tract symptoms, and in one the urinary infection followed a prostatectomy.

Blood Urea and Serum Creatinine.—The blood urea and serum creatinine values at the time of the follow-up study are plotted in Fig. 1. Taking 40 mg./100 ml. as the upper limit of normal for blood urea, 24 patients had elevated levels, the highest being 95 mg./100 ml.

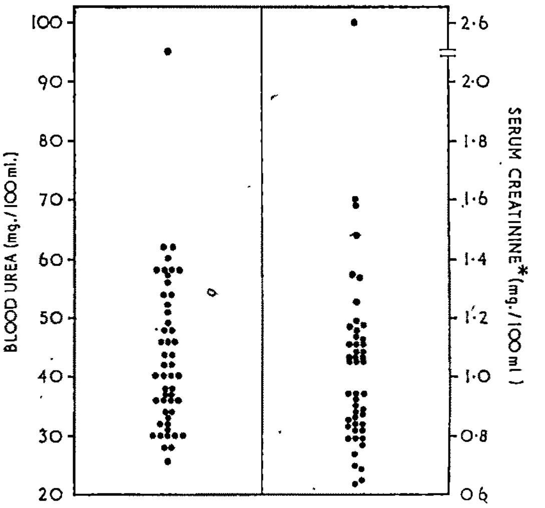

FIG. 1.—Blood urea and serum creatinine levels. *Measured in 48 patients.

Glomerular filtration rate.—The glomerular filtration rates measured by endogenous creatinine and inulin clearances are plotted in Fig. 2. Davies and Shock (1950) have recorded inulin clearances in a large series of normal males related to age, and the inulin clearances in the present study were regarded as normal if they fell within one standard deviation of the mean values of Davies and Shock for each decade. Although a series of comparable size to that of Davies and Shock is not available for females, the data of Homer Smith (1951) show the inulin clearance in females to be approximately 93% of that in males. Normal values for females were therefore arbitrarily taken as being 93% of those quoted for different decades in males by Davies and Shock. Again, the results in the present series were regarded as normal if they fell within one standard deviation of the mean. With the above criteria, 12 of the 41 patients (29%) in whom inulin clearances were performed had normal results.

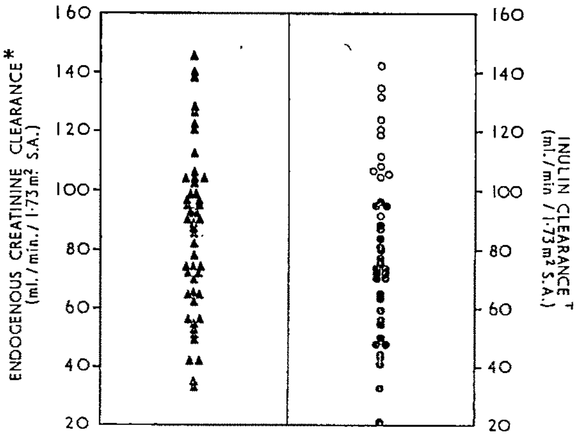

FIG. 2.—Glomerular filtration rate measured by endogenous creatinine and inulin clearance. *Measured in 49 patients. † Measured in 41 patients. ○ Within one standard deviation of. ● More than one standard deviation below, the mean inulin clearance values in normal subjects (Davies and Shock, 1950).

Concentration Test.—Of the 45 patients in whom the concentration test was carried out, 32 (69%) had a value above

1020 after 24 hours' dehydration. A specific gravity between 1016 and 1020 was obtained in six patients (13%), while in the remaining 8 (18%) the value was below 1016.

Modified Acid Load Test.—An inability of the kidney to reduce the urine *p*H to less than 5.4 was found in 14 (33%) of the 42 patients in whom this test was performed. Thirteen of these 14 patients had *p*H values of 5.4 to 5.8 and normal urine titratable acidity and ammonia production. In the remaining patient the urine *p*H was 6.1 with a very high urine ammonia level (101 μEq/min.). The serum electrolytes, however, were normal. The aetiology of this patient's acute tubular necrosis was mercuric chloride poisoning. The normal ranges of urine titratable acidity and ammonia production quoted by Wrong and Davies (1959) were 24 and 33 μEq/min. respectively. In 10 patients (24%) the titratable acidity was less than 24 μEq/min., in six of whom the ammonia production was below 33 μEq/min. Eight of these ten patients had other evidence of generalized renal damage such as lowered glomerular filtration rates, impaired concentration tests, and proteinuria.

Intravenous Pyelogram.—A pyelogram satisfactory for detailed analysis was obtained in 40 patients. The average length of the two kidneys was within normal limits—that is, within one standard deviation of the mean value in relation to body height[1]—in 35 patients (87%). In three patients the average kidney length was 1 to 2 cm. below the mean, while in the remaining two it was more than 2 cm. below the mean. There was a significant difference ($P<0.001$) between the mean glomerular filtration rates of the five patients with small kidneys (54 ml./min.) and that of the 35 patients with kidneys of normal size (91 ml./min.). Calcification of the renal cortex was not observed in any patient, while in one patient with a history of recurrent urinary tract infection before the acute tubular necrosis caliceal clubbing was present.

Interim Follow-up.—In the 14 patients who had both an interim and a formal follow-up study, the mean endogenous creatinine clearances were 87 and 94 ml./min. respectively, the difference not being statstically significant ($P>0.1$). Similarly, there was no significant difference between the mean blood urea values ($P>0.1$). In four of the 14 patients there was impairment of concentrating power at the interim follow-up with a return to normal concentrating power at the time of the formal follow-up, but this could be partly due to the more powerful stimulus of dehydration compared with that of pitressin. Table II summarizes the results of the investigations carried out during the formal follow-up study.

TABLE II.—*Summary of Follow-up Studies*

Type of Test	No. of Patients with Normal Results
Blood pressure	36 (72%)
Urine protein	34 (68%)
„ culture	43 (86%)
Blood urea	26 (52%)
Serum creatinine	32 (of 48) (67%)
G.F.R. (inulin clearance)	12 (of 41) (29%)
Intravenous pyelogram	35 (of 40) (87%)
Concentration test	31 (of 45) (69%)

Discussion

During this study we were impressed with the fact that normal well-being had been restored in almost all patients with a return to their former occupation. In contrast, analysis of the renal function studies showed that in only 13 of 50 patients were all results within strictly normal limits. It is of course likely that in a small number of patients renal function was impaired before the episode of acute tubular necrosis, in particular in the one diabetic patient, in the three patients with hypertension, and in the nine with pre-eclampsia. In the majority of patients, however, there were no features suggesting pre-existing renal damage, and the impairment of function noted during this study is therefore likely to be a consequence of the episode of acute tubular necrosis.

A reduction in glomerular filtration rate was the commonest abnormality, this being found in 71% of patients. This finding is in agreement with that of Lowe (1952) and of Finkenstaedt and Merrill (1956), who noted a reduction in glomerular filtration rate in the majority of their patients. However, in only seven patients (17%) in the present series was the glomerular filtration rate, measured by the inulin clearance, severely depressed—that is, below 50 ml./min.

Since the reduction in glomerular filtration rate was in most cases not associated with proteinuria, it is likely that it is due to some nephrons being totally non-functioning rather than urine being formed by some partially damaged nephrons. The pathophysiology of acute tubular necrosis is disputed: there is histological evidence that the primary change occurs in the tubules (Oliver *et al.*, 1951) and also evidence against this view (Finckh *et al.*, 1962). Support for the concept that the lesion is not limited to the tubules is provided by the study of De Luna *et al.* (1964), which showed that the pattern of acid excretion during the recovery phase of acute tubular necrosis—namely, a slightly raised urine *p*H with very low ammonia excretion—is similar to that seen in generalized renal disease (Wrong and Davies, 1959). The finding by Price and Palmer (1960) that the major histological changes in the kidneys after acute tubular necrosis are in the glomeruli lends support to the theory that the primary abnormality in acute tubular necrosis involves the glomeruli. Studies of animal models have supported the concept that the primary change is a marked drop in glomerular filtration rate (Oken *et al.*, 1966), though subsequent tubular obstruction is also an important factor (Jaenike and Schneeberger, 1966). Direct measurement of renal plasma flow has shown a reduction to about 50% of normal in the early stages of acute tubular necrosis (Reubi *et al.*, 1964 ; Shaldon *et al.*, 1964). Our findings cannot be taken to support either theory of the pathophysiology of acute tubular necrosis, since nephrons will cease functioning if either the glomerular or tubular damage is severe enough. They do, however, support the concept that there are structural changes at least in some nephrons in acute tubular necrosis, rather than simply a functional lesion (Sevitt, 1959 ; Finckh *et al.*, 1962).

Bull *et al.* (1950) suggested that after reaching a maximum value a few months after the episode of acute tubular necrosis there followed a steady fall in glomerular filtration rate. Also in animal experiments in mice, Fox (1967) has described progressive deterioration in renal function, accompanied by reduction in renal size and interstitial fibrosis, after recovery from ischaemic acute tubular necrosis. Our data, derived from comparison of the creatinine clearances at the interim and detailed follow-up, suggest, however, that following the slow improvement which takes place over the few months after the acute tubular necrosis renal function remains stable.

Although a prolonged oliguric phase is usually associated with a higher initial mortality, there was no relation in this study between the duration of oliguria and the degree of recovery of renal function in those patients who survived the acute phase. The results in the present series were also examined to see if there was any relation between the aetiology of the acute tubular necrosis and the degree of recovery. It was found that where pre-eclampsia had preceded the acute tubular necrosis there was a higher incidence of hypertension, proteinuria, and reduced kidney size than in the complete series, though the mean glomerular filtration rate in the patients with pre-eclampsia was not significantly lower than the mean of all 50 patients. A poorer prognosis in patients with pre-eclampsia during the course of the acute tubular necrosis has also been demonstrated by Smith *et al.* (1965). They found a higher mortality when acute tubular necrosis occurred in late pregnancy than in early pregnancy and a high incidence of pre-eclampsia in the former group.

---

[1] These results were calculated by means of the charts of radiographic kidney size prepared by the Department of X-ray Diagnosis, University College Hospital, London, and printed by Kodak Ltd., London.

Hypertension has been noted in a few patients after recovery from acute tubular necrosis (Lowe, 1952; Edwards, 1959; Price and Palmer, 1960). In the present series, of the six patients with diastolic blood pressures of over 100 mm. Hg at the time of follow-up, four had pre-eclampsia and two had pre-existing hypertension. There is therefore no evidence from this study that acute tubular necrosis leads to the development of hypertension.

A high incidence of urinary tract infection during the course of acute tubular necrosis has been recorded in a previous series (Swann and Merrill, 1953) and is confirmed in the present one, significant bacteriuria having been found in 46% of patients. In only six patients, however, was bacteriuria found at the time of follow-up, and in four of these six there was an adequate explanation for the finding (see Results). There is therefore no evidence that acute tubular necrosis per se predisposes to the development of persistent or recurrent urinary tract infection.

The finding that one-third of the patients had urine *p*H values in the range 5.4–5.8 during a modified acid load test is of dubious significance. The patients with low urine ammonia levels and reduced titratable acidity had in addition proteinuria, low glomerular filtration rates, and impaired concentration tests, and the abnormality of acid excretion therefore probably reflected generalized renal damage. The patient whose urine *p*H failed to fall below 6 is of special interest. The cause of his acute tubular necrosis was mercuric chloride ingestion. His serum electrolytes, glomerular filtration rate, and concentration test were normal and the urine ammonia high (101 μEq/min.). These findings are similar to those described by Wrong and Davies (1959) in their patients with incomplete renal tubular acidosis, and it may be that this patient has suffered specific damage to the hydrogen-ion excretion mechanism of his renal tubules.

In conclusion, this study shows that the long-term prognosis is good in patients who survive an episode of acute tubular necrosis. A normal state of health was almost always regained, though detailed investigation of renal function revealed some abnormality in most patients (74%), most commonly a lowered glomerular filtration rate (71%).

Summary

A detailed examination of renal function has been carried out in 50 patients with a previous well-documented episode of acute tubular necrosis. The time interval between the acute tubular necrosis and follow-up varied from 4 to 75 months, but was less than one year in only two cases. All patients at the time of follow-up had made a good clinical recovery and were leading active lives. However, investigation of renal function revealed some abnormality in 37 (74%) of the patients, the most common defect being a lowered glomerular filtration rate (71%). Tests of tubular function were found to be abnormal in a much smaller number of patients, the concentration test being impaired in only 31%. No correlation was found between renal function at the time of follow-up and either the severity of the renal failure or the precipitating cause, but patients in whom pre-eclampsia preceded the acute tubular necrosis did have a high incidence of residual renal damage. There was no evidence that the episode of acute tubular necrosis led to hypertension, any alteration in renal size or caliceal changes, or predisposed to urinary tract infection. Serial studies in 14 patients suggested that no subsequent deterioration in renal function followed the initial recovery.

Paediatric Aspects of the Early Discharge of Maternity Patients

M. W. ARTHURTON,* M.D., M.R.C.P., D.C.H. ; F. N. BAMFORD,† M.B., CH.B., D.C.H., D.P.H.

Brit. med. J., 1967, 3, 517–520

Planned early discharge of mothers and babies from St. Luke's Maternity Hospital, Bradford, has been taking place since 1958. The purpose of this paper is to describe the effect it has had on child health in the city, and, in particular, to consider its safety and acceptability from a paediatric point of view.

Theobald (1959, 1962) depicted the form and purpose of the "Bradford experiment," and Douglas *et al.* (1961) have published the results of the scheme from its inception until the end of 1960. The results of early discharge elsewhere have been described by Hellman *et al.* (1962) and Pinker and Fraser (1964).

Our review covers a period of seven years from January 1959 to December 1965, during which time 9,718 babies were discharged within 72 hours of birth. It is believed that up to the present this represents the greatest numerical experience of planned early discharge in Great Britain. The survey does not include babies taken home early against advice or those discharged to other units, nor to areas outside the city boundary. Full responsibility for neonatal care was accepted by the paediatric department in August 1962.

Results

The total number and the proportion of babies discharged within 72 hours to the city area during each of the seven years is shown in Table I.

TABLE I.—*Babies Discharged Within 72 Hours*

	1959	1960	1961	1962	1963	1964	1965	Total
No. of babies discharged early ..	922	1,176	1,358	1,350	1,669	1,562	1,681	9,718
Proportion of total hospital births discharged early (%)..	37·3	37·0	41·9	39·4	48·7	44·1	47·6	41·6

Mortality

Fig. 1 gives the perinatal mortality rate of Bradford in comparison with the national rate. Of the 9,718 babies who were discharged early 8 (0.82 per thousand) died before they reached the age of 11 days. Out of a total of 15,887 babies born on the district during the same period 20 died between the ages of 2 and 10 days inclusive, giving a comparable mortality rate of 1.26 per thousand. The difference between the two groups is not statistically significant (S.E. (difference), 0.40 ; P=0.24).

Details of the eight babies from the early discharge group who died are as follows:

Case 1.—Tentorial tear: spontaneous occipitoposterior delivery; fourth child; birth weight 9 lb. (4.080 g.). Discharged by obstetric registrar at age 34 hours; readmitted on third day and died next day.

Case 2.—Atrial septal defect with hypoplastic left ventricle and aorta: normal delivery; second child; birth weight 6 lb. 2 oz. (2.780 g.). Discharged by obstetric house-surgeon at age 39 hours; readmitted on eighth day in cardiac failure but with normal heart sounds; died on the following day.

Case 3.—Perforated caecum with peritonitis: normal delivery; third child; birth weight 7 lb. 4 oz. (3,290 g.). Discharged by obstetric house-surgeon at age 29 hours. Vomited blood on the second day; readmitted on the fifth day because of persistent vomiting. Immediate laparotomy with exteriorization of caecum and peritoneal drainage; died five hours later.

Case 4.—Ventricular septal defect: normal delivery; third child; birth weight 8 lb. 5 oz. (3,770 g.). Discharged by obstetric registrar at age 28 hours; readmitted in cardiac failure with a cardiac murmur on the sixth day of life; died on the following day.

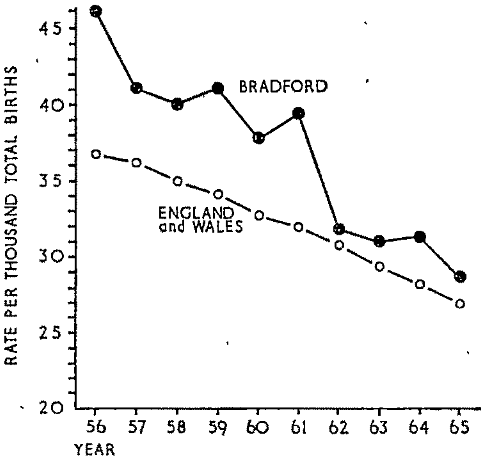

FIG. 1.—Perinatal mortality rates.

Case 5.—Bronchopneumonia: normal delivery; fourth child; birth weight 6 lb. (2,720 g.). Discharged by paediatric senior house-officer at age 32 hours. Midwife subsequently refused admission to house; died at home on the third day.

Case 6.—Fallot's tetralogy: shoulder presentation corrected to vertex; third child; birth weight 8 lb. 6 oz. (3,800 g.). Discharged by paediatric registrar at age 27 hours; readmitted on sixth day of life with peripheral cyanosis, rapid pulse, enlarged heart, but no cardiac murmur or signs of failure; died next day. Necropsy also revealed a small cerebral haemorrhage.

Case 7.—Bronchopneumonia: normal delivery; first child; birth weight 7 lb. (3,175 g.). Discharged by paediatric registrar at age 39 hours. Died at home on the ninth day of life.

Case 8.—Left adrenal haemorrhage: normal delivery; third child; birth weight 6 lb. 5 oz. (2,865 g.). Discharged by paediatric senior house-officer at age 36 hours. Readmitted on the same day; died of peripheral circulatory failure a few hours later.

In addition to the eight babies described above nine who were discharged early died between the twelfth and twenty-ninth days, inclusive. The causes of death were as follows:

Bronchopneumonia	6 babies aged 15 to 25 days
Transposition of great vessels ...	1 baby aged 13 days
Gastroenteritis	1 baby aged 21 days
Tentorial tear	1 baby aged 15 days

The cause of death was confirmed at necropsy in every case.

Morbidity

Of those babies who were discharged early 85 (8.74 per thousand) were readmitted to hospital within the first 10 days, compared with 145 (9.12 per thousand) babies of the same age born on the district and admitted to hospital between the ages of 2 and 10 days inclusive. This difference is not significant (S.E. (difference), 1.21; P=0.75).

---

* Consultant Paediatrician, Bradford.
† Principal Medical Officer in Child Health, Bradford.

The age at the time of readmission of early discharge babies is shown in Fig. 2.

Table II shows the cumulative percentage of early discharge babies readmitted between the ages of 1 and 10 days inclusive.

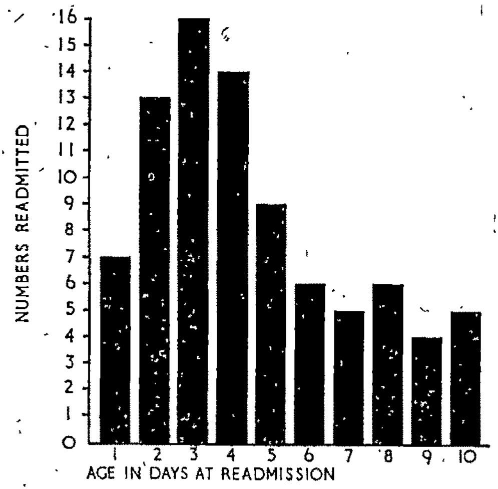

FIG. 2.—Early discharge readmissions (City of Bradford).

TABLE II

Age (days) ..	1	2	3	4	5	6	7	8	9	10
Cumulative % of admissions ..	8	24	42	59	68	76	82	89	94	100

The reasons for readmission of babies are shown in Table III and comparable figures are given for babies of the same age who were born at home and required admission to hospital.

TABLE III.—*Reasons for Readmission*

Diagnosis on Admission/Readmission	No. of Early Discharge Babies	No. of Domiciliary Babies
Infections	21 (24·7%)	41 (28·2%)
Physiological conditions	15 (17·6%)	10 (6·9%)
Feeding problems	9 (10·6%)	16 (11·0%)
Haemorrhagic disease of newborn	9 (10·6%)	9 (6·2%)
Congenital defects	8 (9·4%)	18 (12·4%)
Cerebral injury and irritation ..	5 (5·9%)	13 (9·0%)
Prematurity..		7 (4 8%)
Atelectasis		2 (1·4%)
Miscellaneous	18 (21·2%)	29 (20·1%)

Any early discharge baby readmitted before the age of 48 hours was included in Table III, whereas domiciliary delivered babies admitted before that age were excluded from consideration.

Babies discharged before the age of 24 hours required readmission significantly more often than those sent home on the second day. During the period covered by Craig and Muirhead (1967) 3.7% of mothers were discharged before 24 hours, but 17.6% of the babies readmitted to hospital in the same period had been discharged on the first day of life (S.E. (difference)=5.33%).

Table III gives no indication of the incidence of minor morbidity. An attempt was made to assess this by an analysis of midwives' medical aid request forms, but the differing practice of general practitioners in neonatal visiting and the variable experience of individual midwives made the results inexact. However, during the last two years of the survey 7.4% of the domiciliary group and 2.9% of the early discharge babies were the subject of medical aid calls between the second and tenth days of life.

Breast-feeding

A postal questionary was sent to all women delivered in Bradford in the first six months of 1964 with the exception of those cases where there was an obstetric, paediatric, or social abnormality which could interfere with the establishment or maintenance of breast-feeding. The number of "normal" confinements in the long-stay group was at first insufficient for statistical comparison, and this group was enlarged by the inclusion of similar women delivered during the following 18 months. A total of 743 patients returned the questionary; 515 of these were delivered on the district; 163 stayed in hospital for less than 72 hours and 65 for more than 72 hours (Table IV).

TABLE IV.—*Breast-feeding*

	Domiciliary	Hospital Short-stay	Hospital Long-stay
Percentage of women breast-feeding for one week or more	57 9	67·5	73·8
Percentage of women breast-feeding for six weeks or more	21·0	31·9	23·1

We tried to find out what caused women in each of the groups to discontinue breast-feeding. They were given a choice of six reasons, and were asked to select the one that applied to them (Table V).

TABLE V

	Reasons for Breast-Feeding Less Than One Week (% of Reasons Given)			Reasons for Stopping Breast-Feeding After the First Week (% of Reasons Given)		
	District	Hospital Short-stay	Hospital Long-stay	District	Hospital Short-stay	Hospital Long-stay
Preferred to bottle-feed	54·1	38·3	26·7	12·3	11·6	21·3
Returned to work ..	1·0	1·7	—	1·6	—	—
Illness	1·9	3·3	—	3·8	5·4	2·1
Not enough milk ..	19·3	20·0	26·7	49·3	45·5	61·7
Pain or difficulty ..	23·7	36 7	46·6	21·4	23·2	10·6
Baby old enough to stop	—	—	—	11·6	14·3	4·3

Discussion

Bradford is an industrial city which had a high incidence of toxaemia of pregnancy and a perinatal mortality rate considerably higher than the national average. The original purpose of planned early discharge was to release hospital beds for the treatment of toxaemia without reducing the number of hospital confinements. Since the inception of the scheme there has been an absolute improvement in perinatal mortality and also an improvement relative to the national rate (Fig. 1).

Better facilities for the treatment of toxaemia might have been expected to result in a reduction in the number of premature births, and it is disappointing that this has not occurred. There has, however, been a decrease in the proportion of premature babies of low birth weight—for example, those of 3 lb. 4 oz. (1.475 g.) or less—the total number of which has remained constant despite a rising birth rate.

Unfortunately it is difficult to be certain of the exact effect of early discharge because the figures have been confused by a changing population structure during the seven years of the study, but it is clear that the scheme has had no serious adverse effect and may have contributed to an improvement in child health.

Deaths among babies who were the subject of early discharge have been compared with the number who died between the ages of 2 and 10 days, inclusive, after domiciliary confinement. We believe that this comparison is valid, since domiciliary confinement has been the only practicable alternative for the majority of mothers in the city.

There is no evidence that early discharge offers any advantage for the individual baby as compared with staying in hospital for 10 days, and in fact there are additional risks partly attributable to difficulties in neonatal diagnosis. Some congenital defects and cerebral lesions do not show themselves within the first 48 hours, nor, in the case of one of our late deaths, within the normal 10-day lying-in period. Though it was undesirable, on general grounds, to have discharged the eight babies who subsequently died, it is unlikely that early discharge adversely affected the chances of survival of Cases 1 and 2. Early discharge was ill-advised in Cases 3 and 6. None of the nine deaths occurring after 10 days could be related to early discharge.

The longer a baby remains in hospital the less likely it is that pathological lesions will be undetected before discharge. It is preferable to avoid the need for readmission, and in our experience this would be reduced by 59% if mothers and babies left hospital on the fifth day (Fig. 2). Unfortunately, this would not be practicable without a fundamental reorganization of the maternity services. At present such an arrangement might lead to a false sense of security, because the interest taken by domiciliary midwives could be inversely proportional to the length of hospital stay of the baby. Furthermore, it would be sensible to discharge breast-fed babies as early as possible so that the early phases of feeding could be supervised by one adviser.

The incidence of feeding problems severe enough to warrant readmission was virtually the same in the two groups of babies, though a survey by members of the College of General Practitioners (1966) did show a higher incidence of minor feeding problems in their early discharge group. In our review of the early discharge babies readmitted five were underfed on the breast, two mothers lost their milk owing to emotional disturbance, and in one case faulty technique in artificial feeding was noted.

It was noticeable and understandable that in the early years of the survey a greater proportion of early discharge babies were readmitted with physiological conditions, including swallowed-blood syndrome, vaginal bleeding, urates in the urine, and physiological jaundice. There was a statistically significant difference ($P<0.05$) in admission rates for these conditions between the early discharge and domiciliary groups (see Table III).

As might have been anticipated, cases of haemorrhagic disease were readmitted early, two-thirds of them by the third day and all of them by the fifth day of life.

Babies with congenital defects who were readmitted consisted of five with congenital heart disease and three with hiatus hernia. In only one case of the former was a murmur heard on readmission. Careful perusal of admissions to the genito-urinary department during the period of the survey failed to reveal any missed cases of obstructive lesions of the genito-urinary tract, though such cases could easily be missed in the first two days of life.

Two cases of subarachnoid haemorrhage (one fatal), one case of subdural haemorrhage, and two babies with cerebral irritation were readmitted. The fatal case was an occipitoposterior delivery, and in one case of cerebral irritation delivery was by low forceps. Otherwise the confinements were normal. The number of cerebral complications did not differ significantly between the two groups of babies.

Unfortunately, owing to differences in methods of ascertainment by different observers and lack of strictly comparable groups, it was not possible to compare the incidence of infection in babies delivered at home, those discharged early, and those remaining in hospital for 10 days, many of the latter group being abnormal deliveries. The readmission rates for infection in the first two groups did not differ significantly. It is noteworthy that during the period of the survey four cases of gonococcal ophthalmia of late onset were observed in babies staying in hospital for 10 days.

Included in the miscellaneous group were convulsions (4), choking attacks (3), anal excoriation (2), haemolytic disease of the newborn due to rhesus incompatibility (2), and one case each of left adrenal haemorrhage (fatal), congenital spherocytic anaemia, hypothermia, meconium plug, perforated caecum (fatal), pyloric stenosis, and urticaria. No cause was found for the convulsions, and the deliveries of all these cases were normal. The two babies with haemolytic disease and one with meconium plug were erroneously discharged by junior hospital staff. Reference has already been made to the fatal cases.

Prior consultation between general practitioner and paediatrician would have made unnecessary the readmission of 18 (21%) cases in the early discharge group. A further eight babies who were readmitted had been erroneously discharged early because of faulty judgement. Thus there remained 59 babies in our series whose readmission would have been unavoidable, and it is therefore desirable to have special accommodation reserved so that mothers and babies can be readmitted together.

The Cranbrook Report (Ministry of Health, 1958) and the *British Medical Journal* (1964) suggest that early discharge adversely affects breast feeding, but this is contrary to our experience. In this city, of "normal" women delivered in hospital a greater proportion breast-fed for one week or longer than did women confined at home, and relatively more of them continued to feed for six weeks or longer. The differences between the short-stay and domiciliary groups are highly significant and pertain to all ages. It was shown that, though more of the younger mothers start to breast-feed—that is, feed for one week or more—a greater proportion of older mothers become established breast-feeders—that is, feed for six weeks or more. Social class was not significant in determining the number of women starting to breast-feed, but feeding was shown to become established more frequently in social groups I and II. The difference between the early discharge and long-stay hospital groups was not statistically significant.

A disturbing finding in the breast-feeding survey was that relatively more women delivered in hospital discontinued feeding after less than one week because of pain or difficulty (see Table V). Of those confined in hospital who fed for one week or longer the proportions in the early discharge and long-stay groups are about equal, which suggests that the disparity is due to an adverse influence in hospitals and that it is not assisted by the mother remaining for 10 days.

An early discharge scheme of the type that has been in operation in Bradford during the past seven years can be operated with advantage to the neonate, and he suffers no disadvantages as compared with the baby born on the district. We would emphasize, however, that the arrangements have to be planned in advance, and that close and continuing co-operation is necessary between all people concerned. Success depends on the competence and reliability of midwives, nurses, and junior medical staff, who carry out 10 or more routine neonatal examinations every day of the year. An efficient neonatal follow-up clinic is vital, as is the willingness of the paediatrician to deal promptly and personally with the medical and social consequences of neonatal abnormality. Provided that this degree of effort is made, the scheme can be safe and effective.

Summary

During 1959 to 1965, inclusive, a total of 9,718 babies were discharged from hospital within 72 hours of birth. An improvement in perinatal mortality has been described, and the mortality and morbidity experience of "early discharge" babies has been compared with those born at home during the same period. The difference between the two groups was not statistically significant. An inquiry into breast-feeding in the domiciliary,

early discharge, and long-stay hospital patients is recorded; it has shown that mothers confined in hospital begin to feed their babies and become established breast-feeders more often than do women delivered at home.

We wish to thank Dr. A. P. Roberts for permission to review cases in his care; Miss G. Clayton, Matron of St. Luke's Maternity Hospital, and Miss E. R. Entwhistle, Supervisor of Midwives, for their invaluable help on numerous occasions; and Dr. G. Hill for statistical advice. We wish to pay tribute to a very loyal junior staff.

Obstetric Aspects of the Early Discharge of Maternity Patients

Brit. med. J., 1967, **3**, 520–522

It is now nine years since planned early discharge of the normal mother and normal baby on the second day of the puerperium was commenced in Bradford. The scheme has since been in continuous operation, and to date approximately 13,000 puerperal women have been managed in this way. Theobald (1959, 1962) and Douglas *et al.* (1961) described the reasons for and the initial planning of the scheme, and recorded its early results. In 1966 members of the College of General Practitioners (Bradford group) reported on a survey of 100 early discharge cases.

Five thousand consecutive case records have been analysed in order to show the types of patients that have participated in the scheme. Abnormalities that occurred but which were not thought sufficiently important to warrant retaining the patient in hospital for longer than 60 hours have been recorded. The purpose of the paper is to present these results, and it also includes a discussion of our experience.

Patients Discharged Early

Of the 5,000 patients whose records were analysed 70% were booked for hospital confinement and 30% were emergency admissions either during the antenatal period or during labour. The age distribution is recorded in Table I. The number of women in each parity group is shown in Table II. The length of stay in hospital of the 5,000 patients is given in Table III.

TABLE I.—*Age Distribution of Patients Discharged Early*

Age Group	Primigravidae	Multigravidae
Under 20 years	421 (8·4%)	89 (1·8%)
20–24 years	644 (12·9%)	695 (13·9%)
25–29 years	320 (6·4%)	1,028 (20·6%)
30–34 years	136 (2·7%)	848 (17·0%)
35 years and over	30 (0·6%)	789 (15·8%)

TABLE II.—*Parity Distribution of Patients Discharged Early*

No. (%)	1,551 (31)	1,300 (26)	818 (16·4)	498 (10)	833 (16·7)

TABLE III.—*Patients' Duration of Stay in Hospital*

Duration of Stay	Primiparae		Multiparae		Total	
	No.	%	No.	%	No.	%
Patients discharged in less than 24 hours ..	56	1·1	127	2·5	183	3·7
Patients discharged in 24–36 hours.. ..	1,094	21·9	2,450	49·0	3,544	70·9
Patients discharged in 36–60 hours.. ..	401	8·0	872	17·4	1,273	25·4

The original policy was to discharge on the second day those mothers and babies whose condition did not seem to justify further hospital care. A number of women who had had abnormalities during labour or at the time of delivery have participated in the scheme. The incidence of intrapartum complications in the 5,000 patients whose records were analysed is shown in Table IV. The complications that occurred at the time of delivery in patients discharged early are recorded in Table V.

TABLE IV.—*Intrapartum Complications in Patients Discharged Early*

Intrapartum Complication	Primigravidae	Multigravidae
Artificial rupture of membranes ..	512 (10·2%)	916 (18·3%)
Oxytocin drip	84 (1·7%)	197 (3·9%)
Pyrexia 99–99·8° F. (37·2–37·7° C.) on two or more occasions ..	17 (0·3%)	38 (0·8%)
Pyrexia 100° F. (37·8° C.) and over	3 (0·06%)	9 (0·2%)

TABLE V.—*Complications at Time of Delivery in Early Discharge Patients*

Complication	Primigravidae	Multigravidae
Ruptured perineum	520 (10·4%)	866 (17·3%)

Postpartum haemorrhage with transfusion	2 (0 04%)	9 (0·2%)

Hospital Organization

The early discharge scheme has resulted in a considerable increase in the work done in the hospital. St. Luke's Maternity Hospital is the only maternity hospital in Bradford. It was designed to manage approximately 1,500 confinements a year. Before the introduction of the scheme in 1958 this figure had risen to 2,000 a year and since then it has continued to rise until in 1964 it almost reached 4,000. Such an increase imposes a very severe strain on all members of the hospital staff, particularly those engaged in the labour ward. In such circumstances it is difficult to maintain standards and the continuous

---

* Consultant Obstetrician and Gynaecologist, Bradford.

supervision that is necessary. It was therefore necessary to review the existing arrangements within the hospital and to effect any changes that would help a willing and competent nursing staff, whose numbers were inadequate, to meet the increased demands made upon them.

Ward clerks and ward and theatre orderlies have been appointed as liberally as our financial resources permit in order that the nursing staff may be relieved, so far as is possible, from all non-nursing duties. The labour ward of 12 beds is at the time of writing staffed with six sisters, six midwives, five pupil midwives, two ward clerks, four theatre orderlies, and five ward orderlies. Staff rotation between the various wards is practised. The theatre is now in charge of a sister who is not a midwife. This particular innovation has been a success. So far as is possible, all operative procedures and abnormal deliveries are performed in the operating-theatre.

Patients in labour are admitted direct to the labour suite, which is situated on the ground floor of the hospital. This suite has accommodation for 12 patients in labour, has two delivery rooms, an anaesthetic room, and an operating-theatre. Continuous with the labour suite is a recovery ward of 12 beds. Patients who are thought to be suitable for early discharge are accommodated in the recovery ward until the decision to discharge or not to discharge them is made.

If for any reason a patient and her baby are not discharged early they are immediately transferred to one of the lying-in wards. Those mothers who are to remain in hospital for 10 days are usually transferred from the labour ward to one of the lying-in wards shortly after their delivery has been completed. If, however, it is thought that their condition after delivery warrants continued close supervision then they are accommodated in the recovery ward until their condition has improved sufficiently to warrant their transfer to a lying-in ward. As a result of this reorganization the acute work of the hospital is accommodated on one floor and there has been a considerable reduction in the movement of patients within the hospital. It has also facilitated both medical and nursing arrangements.

We have been greatly impressed with the advantages that have resulted from a centralized labour ward, with adjacent delivery room, operating-theatre, and recovery room. We believe that single rooms should be provided for women in labour and that these should be large enough to allow normal deliveries to be conducted in them. Such an arrangement would reduce the movement of patients within the hospital and make it much easier for those who wish to have their husbands with them during labour.

It is undoubtedly better if patients who are expected to be discharged early are not accommodated alongside those who have to remain for 10 days.

Results

Mortality.—There have been no maternal deaths.

Readmission.—The incidence of readmission has been compared with the admissions to hospital of patients confined in their own homes (see Fig. 1). The most common indications for readmission were persistent bleeding from the uterus and delayed involution. A few patients were readmitted with pyrexia. Those who were readmitted were not dangerously ill and responded rapidly to appropriate treatment.

Eclampsia.—The number of cases of eclampsia that have occurred in patients booked for confinement in St. Luke's Maternity Hospital during the years 1948–65 inclusive is shown in Fig. 2. Since the inception of the early discharge scheme the number of patients booked for confinement in the hospital has risen by nearly 50%, and the admissions of patients with hypertension, proteinuria, and oedema have increased. The majority of the latter are counted as booked patients unless delivery occurred shortly after admission. Despite this, the incidence of eclampsia in booked patients has not gone up and has remained consistently below that of non-booked patients.

Table III shows that it has not been possible to discharge all patients on the morning of the second day; in nearly all cases the decision to discharge a patient in less than 24 hours was taken because beds were urgently required. Patients whose discharge was delayed until the morning of the third day included those whom it had not been possible to get home by midday on the second day and some about whom our information on their home conditions was incomplete or in need of verification.

Discussion

The Bradford scheme has had a mixed reception from those engaged in obstetrics. Some are opposed to it (Claye, 1964; Corbett, 1964; Annual Report of the Health of Kingston-upon-Hull, 1964). Others have accepted it with reluctance, without conviction, and as an emergency measure whereby inadequate obstetric services could be enabled to meet the demands of the population explosion, until such times as adequate hospital, nursing, and medical facilities became available (Ministry of Health, 1958; Report of the Maternity Services Emergency Informal Committee 1963; *B.M.J.*, 1964). A third group appears to have accepted the scheme as being a safe and practical way of managing the normal mother and normal baby once the hazards of confinement are over (Douglas *et al.*, 1961; Hellman *et al.*, 1962; Rhodes, 1964; Pinker and Fraser, 1964).

The early discharge of patients who have had abnormalities is probably the most reasonable basis of criticism, but our results have shown that early discharge can take place without apparent detriment to the patient or her baby, even though certain abnormalities have occurred during the process of labour and delivery.

St. Luke's Maternity Hospital continues to make frequent use of artificial rupture of the membranes not only as a method of induction but also to help labour to become established. The oxytocin drip is used when necessary. It is not thought that the need to use either or both of these procedures precludes early discharge if the condition of the mother and baby is satisfactory after delivery.

Pyrexial patients were not discharged if the pyrexia persisted after delivery. The wisdom of discharging patients who have been pyrexial during labour may be questioned, but there has been no reason to regret the decision taken in the 67 patients included in this inquiry. Our policy has been to repair all ruptured perineums with catgut, in order to avoid the necessity for suture removal at home. This policy has worked well, and wound healing has been satisfactory. If the forceps or the ventouse has been used to deliver the head from the pelvic outlet early discharge takes place if the baby's condition is satisfactory. This is not considered wise if operative delivery has been effected from the mid-cavity of the pelvis. Many babies in the latter group do not show signs of abnormality on the second day. The great majority of these could be discharged early with safety, but a few could not, and the paediatrician obviously requires more time before he can feel confident that intracranial injury has not occurred. For the same reasons the early discharge of all babies delivered by the breech has now been discontinued.

The analysis showed that 36 of the 5,000 patients had some form of cardiac disability. They were all "stage I cardiacs," who had been well throughout their pregnancy and labour and on the first two days of the puerperium. Their discharge was necessary in order to release beds for incoming patients, and, though none of them is known to have suffered any ill effect as a result of early discharge, it is not recommended that cardiac patients should participate in the scheme.

Readmission rates are a good index of morbidity among patients discharged early. The provision of suitable accommodation for mothers with their babies when readmission is necessary is obviously desirable irrespective of whether early discharge is practised or not. It is unfortunate that St. Luke's Maternity Hospital has not yet got suitable accommodation to permit this to be done. An attempt to compare the medical state of a group of early discharge mothers with that of a group of mothers confined at home has not been pursued, as very soon it was apparent that valid conclusions could not be reached because of the many variable factors encountered.

It is desirable that the patient should be home by midday, as this allows ample time for the domiciliary midwife to assure herself that the mother and baby are satisfactorily settled. Patients are transferred as sitting patients, two per ambulance. They are accompanied by a part-time midwife employed by the local health authority. A few patients go home by private transport.

Doubts have been expressed that the Bradford scheme would interfere with the training and attitude of midwives. In our experience this has not been so. The local health authority has been able to maintain a full quota of domiciliary midwives, and on occasion has a waiting-list of women who wish to join the service. The hospital has never found it necessary to close beds because of staff shortages, and, while it is true that the staffing position is never fully satisfactory, difficulties were being experienced long before the introduction of planned early discharge. The existing administrative arrangements for the maternity services make it difficult to achieve the close and continuous co-operation between the three branches of the service that is necessary to ensure the continuity of medical and nursing care which is essential if planned early discharge is to be successful. If it is accepted that early discharge is a safe procedure then future policy should take into account the wishes of the patient regarding her place of confinement, provided that her medical and obstetric state is satisfactory.

An inquiry was made during 1964–5 of 225 women who had had normal confinements in hospital. Of these, 161 remained in hospital for less than 72 hours, and 64 of them for 10 days. They were asked to state where they would have preferred to have their baby: 50% of the 10-day group and 43.5% of the 2-day group were satisfied with their place of confinement (S.E. (Diff.) = 7.4%—that is, a difference that is not significant). No marked difference in preference was noted in the different age groups and there was no statistically significant difference expressed by women in different social classes. An earlier inquiry of the 161 women who had been confined in hospital and discharged in less than 72 hours showed that 44% of them were satisfied with the arrangements.

Early discharge has many attractions for the high-risk multigravidae, who are not infrequently reluctant to be admitted to hospital.

Our experience has shown that it is not necessary for 40–50% of puerperal patients to occupy a hospital bed for 10 days if their homes are suitable and adequate, and medical and nursing care can be provided for them. It has been alleged that early discharge of the puerperal patient from hospital means that she will return to her full range of domestic duties immediately. There is no reason why she should do so to any greater extent than those women who have been confined at home, and it may even be that the earlier ambulation and performance of light household duties are beneficial. There is no reason why the quality of postnatal care provided by the family doctor and the domiciliary care should be inferior to that provided in hospital.

Summary and Conclusions

The case records of 5,000 consecutive patients who were discharged from hospital within 60 hours of delivery have been analysed. Our experience has been that planned early discharge does not result in increased maternal morbidity nor does it add to the maternal risk. Modifications in the internal arrangements and staffing of the hospital have been described.

The scheme has proved to be an efficient and economic way of ensuring that the maximum number of mothers and babies receive the benefit of hospital care at the time of their greatest need for it.

An appreciable number of patients like and request early discharge. It is to be hoped that this will be recognized by the various authorities and that a more flexible approach to the management of the first 10 days of the puerperium will become the accepted rule.

We are indebted to the Leeds Regional Hospital Board for a grant to enable the analysis of the patients' records to be carried out. Thanks are due to our colleague, Mr. A. C. Muir, who kindly gave permission for the records of patients under his care to be included in the analysis. In addition, we have received valuable help from Mr. Haley, the Secretary, from Miss Clayton, Matron of St. Luke's Maternity Hospital and her staff, and from Mr. H. A. H. Melville. We also wish to express our appreciation for the help given by the Health Department of the City of Bradford.

Urinary Steroid Assays and Response to Endocrine Ablation

B. S. THOMAS,* M.I.BIOL.; R. D. BULBROOK,* M.SC., PH.D.; J. L. HAYWARD,† M.B., B.S., F.R.C.S.

Brit. med. J., 1967, 3, 523–524

Bulbrook, Greenwood, and Hayward (1960) found a close relation between the subsequent clinical response of patients with advanced breast cancer to endocrine ablation and the amounts of androgen and corticosteroid metabolites in the urine before operation. They noted that in their small series of patients the best correlation between steroid assay results and clinical response was obtained if a discriminant function was used. This function was: 80-80 (17-OHCS mg./24 hours) + aetiocholanalone (μg./24 hours). The function is positive in patients excreting large amounts of aetiocholanolone relative to the amounts of 17-OHCS, and patients in this category generally responded well to endocrine ablation. Conversely, patients in whom the discriminant is negative (low aetiocholanolone excretion relative to that of the 17-OHCS) generally do not benefit from adrenalectomy or hypophysectomy (see Hayward and Bulbrook, 1965).

Miller, Durant, Jacobs, and Allison (1967) have described a high degree of correlation between the discriminant and a simple ratio of the total urinary 11-deoxy-17-oxosteroids and the 17-OHCS. It should follow, therefore, that their ratio would be as useful as the discriminant in the prediction of response to adrenalectomy or hypophysectomy.

We had available the assay results of the total 11-deoxy-17-oxosteroids, the 17-OHCS, and the discriminant in 210 patients with advanced breast cancer whose clinical response to endocrine ablation was already known. This paper is a report of a retrospective comparison of the predictive value of the discriminant and of the ratio described by Miller *et al.* (1967).

Methods

The 17-OHCS were determined by the method of Appleby, Gibson, Norymberski, and Stubbs (1955). It should be noted that Miller *et al.* (1967) used the method of Metcalf (1963) for the determination of the 17-OHCS. These methods are not strictly comparable: the latter method is based on a short-term hot oxidation of the 17-OHCS with sodium metaperiodate and the results are expressed in cortisol equivalents. The method of Appleby *et al.* (1955) is based on oxidation at room temperature with sodium bismuthate and results are expressed in terms of dehydroepiandrosterone. In practice, this means that the results of the 17-OHCS assays may differ by 1–2 mg./24 hours, but the difference between the methods should be approximately constant (see, for example, Thomas, 1965).

In the first 119 patients dehydroepiandrosterone, androsterone, and aetiocholanolone were determined by the method of Kellie and Wade (1957) and the value for the total 11-deoxy-17-oxosteroids was obtained by summing the amounts of these three steroids. In the remaining patients the total 11-deoxy-17-oxosteroids were measured as a group by the method of Thomas and Bulbrook (1964). The results of the two methods are very similar.

Either three or five consecutive 24-hour urine specimens were collected from 210 patients with metastatic breast cancer awaiting combined oophorectomy and adrenalectomy, or hypophysectomy. Clinical evaluation of response to treatment has been described in detail by Hayward and Bulbrook (1965) and the methods used have been discussed at length (see Hayward and Bulbrook, 1966).

Results

The usefulness of the discriminant function in differentiating between responsive and unresponsive patients at adrenalectomy or hypophysectomy can be judged from the data in the Table. In this series of 210 patients the remission rate is three times as great in patients with positive discriminants as in those with negative discriminants.

Relation Between the Response of Patients with Advanced Breast Cancer to Adrenalectomy or Hypophysectomy and the Discriminant Function

	Discriminant Positive		Discriminant Negative	
	No.	%	No.	%
Success	41	38·7	12	11·5
Intermediate	26	24·5	29	27·9
Failure	39	36·8	63	60·6
Total	106		104	

χ^2 for trend = 19·91. $P < 0{\cdot}001$.

The relation between the clinical response of patients to adrenalectomy or hypophysectomy and either the discriminant function or a ratio of the total 11-deoxy-17-oxosteroids to the 17-OHCS is shown in Fig. 1. It can be seen that the majority of successful responses to treatment occur in patients with positive discriminants and with high ratios. Conversely, the

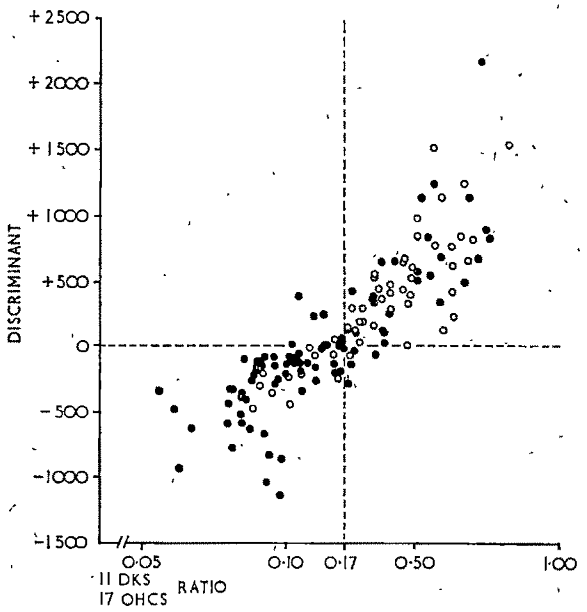

FIG. 1.—Relation between clinical response to adrenalectomy or hypophysectomy and the discriminant function or the 11-deoxy-17-oxosteroid/17-OHCS ratio. This Figure is based on results from 197 patients, of whom 52 responded to treatment and 92 failed to respond. ○ = Successful response. ● = Failure.

---

* Division of Chemistry and Biochemistry, Imperial Cancer Research Fund, London W.C.2.

† Department of Surgery, Guy's Hospital, London S.E.1.

majority of the failures occur in patients with negative discriminants and low ratios. If a ratio is used such that

$$\frac{\text{11-deoxy-17-oxosteroids (mg./24 hours)}}{\text{17-OHCS (mg./24 hours)}} = 0.17$$

then patients with ratios equal to or below this figure have a response rate that is identical to that found for patients with negative discriminants. Similarly, patients with a ratio above 0.17 also have a response rate that is virtually the same as that for patients with positive discriminants (see Fig. 2).

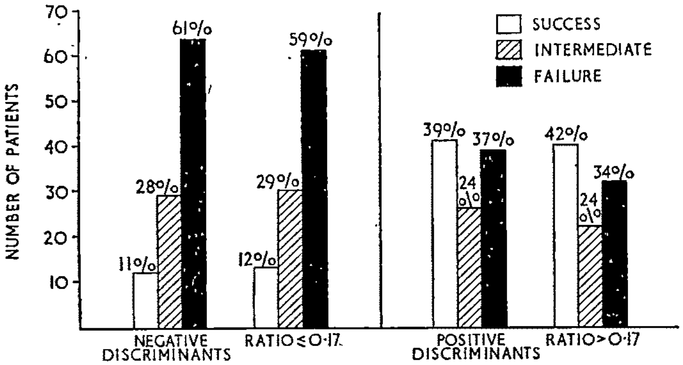

FIG. 2.—Clinical response to endocrine ablation in relation to discriminant or ratio of 11-deoxy-17-oxosteroids to the 17-OHCS.

Discussion

The results in this paper show that a simple ratio of the 11-deoxy-17-oxosteroids to the 17-OHCS can be chosen which in retrospect will give the same prediction of response to endocrine ablation as the discriminant function. This finding is to be expected from the results of Miller *et al.* (1967). It should be recalled that the discriminant function was calculated originally from the results of an investigation of a small series of 59 patients, of whom only 14 responded to treatment. The misclassification of only one or two of these successful cases would have had a pronounced effect, and a discriminant function gave the best separation of responsive and unresponsive cases at that time.

The easier analytical methods used by Miller *et al.* (1967) could be substituted, therefore, for the more cumbersome ones required for the calculation of the original discriminant for patients with advanced breast cancer.

There is a considerable degree of misclassification of response, whether the discriminant or the ratio is used. The results in the Table show that 37% of patients with positive discriminants fail to respond to treatment, whereas 12% of patients with negative discriminants enjoy an objective remission of the disease. To a very large extent the same patients are misclassified by the ratio or by the discriminant.

While there is now a considerable consensus of agreement that the response of patients to adrenalectomy or hypophysectomy is related to the amounts of androgen and corticosteroid metabolites found in the urine before treatment, the results of individual workers differ in detail and emphasis. Thus, Juret, Hayem, and Flaisler (1964) found that the sum of the androsterone and aetiocholanolone values was related to the response of their patients to destruction of the pituitary by yttrium-90.

Wilson, Crocker, Fairgrieve, Bartholomay, Emerson, and Moore (1967) have found a relation between clinical response to adrenalectomy and a discriminant function based on 17-oxosteroid and 17-OHCS response to A.C.T.H. stimulation, and they also make use of the predictive information provided by the free period (see below). Kumaoka, Abe, Sakauchi, Takatana, and Kusama (1966) have found significant differences in total 17-oxosteroid excretion between their responsive and unresponsive patients.

An additional complication is the recognition that factors other than the endocrine environment are of considerable importance in relation to response to treatment. The free period (the time between mastectomy and first recurrence of the disease) is longer in responsive patients than in unresponsive patients (see Taylor, 1966). When the length of the free period is taken into account in conjunction with the steroid assay results, there is a considerable increase in the accuracy of prediction of response. The menopausal status of the patient is also important (see Bulbrook, 1966). Whether the ratio described by Miller *et al.* (1967) will be as useful as the discriminant when employed in conjunction with such factors in patients with advanced breast cancer has yet to be determined.

The most probable development in the future is likely to be the development of even more complicated methods of discriminating between responsive and unresponsive patients as the importance of steroids other than the androgens and corticoids is recognized and as the effect of biological variables such as free period and menopausal status are appreciated.

Bulbrook, Hayward, and Thomas (1964) found that the discriminant function was related to recurrence and death rate after mastectomy. The use of a simple ratio instead of the discriminant in these patients is now being evaluated.

Summary

In women with breast cancer there is a high degree of correlation between the urinary discriminant function 80–80 (17-OHCS mg./24 hours) + aetiocholanolone (μg./24 hours) and a simple ratio of total 11-deoxy-17-oxosteroids to the 17-OHCS.

In a retrospective study on 210 women with advanced breast cancer subjected to either adrenalectomy or hypophysectomy the prognostic values of both the discriminant function and the simplified ratio were virtually identical.

Easier analytical methods are used for the calculation of the 11-deoxy-17-oxosteroid : 17-OHCS ratio than for the calculation of the discriminant function.

Effect of Cyclandelate on Mental Function and Cerebral Blood Flow in Elderly Patients

J. A. C. BALL,* M.D., B.SC., M.R.C.P.ED. ; A. R. TAYLOR,† M.A., M.B., F.R.C.S.

Brit. med. J., 1967, 3, 525–528

There is no demonstrable impairment in the ability of the cerebral blood vessels of elderly subjects to dilate in response to physiological stimuli (Lassen, 1959), but there is general agreement that chemical agents are relatively ineffective in producing such dilatation. Recently, however, reports have appeared that dilatation of cerebral vessels has occurred in response to cyclandelate (Eichhorn, 1965 ; Kuhn, 1965), and there is some uncontrolled evidence that cyclandelate produces an improvement in mental function in elderly patients (Drift, 1961 ; Ravina, 1963 ; Ward, 1964).

As the production of a substantial improvement in mental function in elderly patients would be of inestimable value, a controlled trial of cyclandelate has been made so that its effect on mental function and cerebral circulation in elderly patients could be investigated.

Present Trial

Selection of Patients.—From a population of approximately 200 patients in the long-stay wards of Wakehurst House, the Geriatric Unit of the Belfast City Hospital, 32 were selected whose disabilities were static and who were not so deaf, blind, or demented as to make the mental function tests used unsuitable. There were nine men (average age 75.6 years, range 57–98) and 23 women (average age 76.9 years, range 50–89).

Method.—The 32 patients were divided into two groups of 16 by randomly allocating to each either cyclandelate or placebo. Before the trial began one of us (J. A. C. B.) made a full clinical examination and carried out mental function tests on all the patients. Within 24 hours of the mental function tests mean cerebral circulation time was measured by the other of us (A. R. T.). The patients in group A were then given a 200-mg. tablet of cyclandelate and those in group B an inert tablet identical in size, shape, and colour four times daily for four months. Until the trial was completed only the hospital pharmacist knew which tablets contained cyclandelate.

Mental function tests and radiocirculograms were repeated after two months and again after four months.

Mental Function Tests

The tests used were chosen to illustrate as many aspects of mental function as possible. As most of the patients in the trial had considerable mental impairment only simple tests could be used. Each test consisted of a series of simple questions and a set of simple tasks, and took about 30 minutes to complete.

The questions were similar to those used by Isaacs and Walkey (1964) and determined spatial, temporal, and personal orientation. Short-term memory was assessed by the method of paired associates (Isaacs and Walkey, 1964). Constructional skill and spatial orientation were estimated by means of building blocks and a pegboard (Isaacs and Walkey, 1964 ; Adams and Hurwitz, 1963). To provide a measure of reason, imagination, and verbal expressive ability, the patients were asked to differentiate between a pond and a stream and between a ladder and a staircase and to describe a series of picture absurdities (Terman and Merrill, 1955).

In the final part of the mental function test patients were asked the battery of questions described under the headings of clinical sensorium test (Part 1), clinical questionary, and memory questionary used in the Institute of Psychiatry at the Maudsley Hospital for assessment of mental function in elderly patients (Shapiro *et al.*, 1956). These questions examined separately general orientation, memory for past personal events, memory for recent personal events, memory for general events, and ward orientation.

With the questions and the paired associates, one mark was given for each correct answer. In the tests with the building blocks and the pegboard, additional marks were given when assembly was completed quickly, and marks were deducted when demonstration or assistance was necessary or when the task was not finished within a set time.

Answers to the questions about differences and the responses to the picture absurdities were given up to five marks each, according to how close they came to predetermined levels of accuracy and appropriateness.

The scores obtained in the tests were dependent on the patient's alertness, concentration, and co-operation, but not on special skill, educational background, or social status.

Cerebral Circulation Time

The criterion adopted and thought to be the best simple indicator of blood flow was the mean circulation time (M.C.T.). This was obtained by the method described by Oldendorf (1963). In this, 50 μCi of ^{131}I Hippuran (iodohippurate) is rapidly injected to an antecubital vein and a stream or bolus of radioactivity approaches the head through the carotid and vertebral vessels after passage through the heart and lungs and holds together for one circulation through the cerebral blood pool. Its passage is detected by a collimated crystal directed through the inion towards a point 1 in. (2.5 cm.) above the nasion. Impulses are amplified and passed via a ratemeter to a pen-recorder. A typical curve of counts per second with time is seen in the upper part of Fig. 1. The height P (peak activity) is an indication of the flow rate, as are the angles of rise and fall of the curve. When the first order derivative of the activity curve is drawn, however, as in the lower part of Fig. 1, more accurate measurements can be made. This second curve shows the rate of change of activity with time and has positive and negative peaks indicating maximum rates of change in a positive and negative direction. These two points correspond to the passage of the dense central part of the bolus to and from the scanned area. The interval between the two points is the mean carotid-to-jugular time (M.C.T.). This is the time taken by the average blood cell to cross the cerebral blood pool, and varies in inverse ratio to the cerebral blood flow.

That there are many such times was shown by Nylin *et al.* (1960), who injected ^{32}P-labelled red cells into the carotid

† Neurological Surgeon, Royal Victoria Hospital, Belfast.

artery and monitored the radioactive stream in both jugular veins by mechanical sampling once every second. The first cells arrived in 1–2 seconds, and the last in 12–15 seconds. The average M.C.T. found by Nylin *et al.* in a group of normal patients was 7.3 seconds (standard error 0.9 second). This closely corresponds to an average M.C.T. of 7.41 seconds (S.E. 0.1 second) found here in a group of normal patients whose mean age was 32 years (Taylor and Bell, 1966).

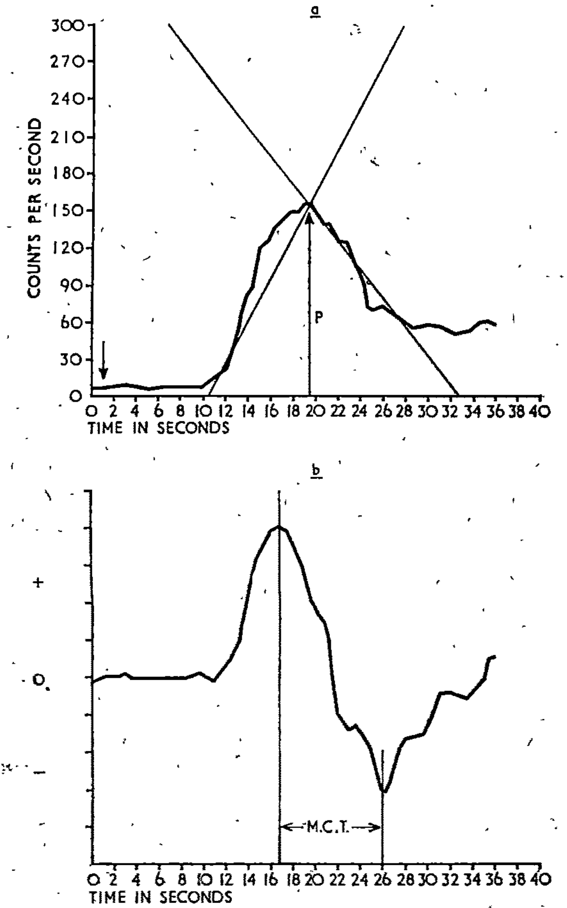

FIG. 1.—(a) Normal radiocirculogram. (b) Differentiated curve.

Course of the Trial

Three patients refused to take their tablets shortly after the trial began. Two of them were on cyclandelate and one on placebo. Four patients died during the course of the trial; one was on cyclandelate and three were on placebo. One patient on placebo was too ill at the end of the first trial period for mental function testing to be possible. Mental function tests were thus completed on three occasions on each of the remaining 24 patients, 13 of whom were on cyclandelate and 11 on placebo.

One patient who had completed four months' treatment with cyclandelate had a right cerebral thrombosis on the morning after her mental function test. The results of this test have been included in the analyses, but further cerebral circulation studies were not made. Another patient, also on cyclandelate, had a technically unsuccessful radiocirculogram, the results of which could not be analysed. Three successful radiocirculograms were thus performed on each of 22 patients, 11 of whom were on cyclandelate and 11 on placebo.

Results

In all the analyses a result is termed significant when the probability of its occurrence by chance is less than 0.05.

Comparison of the ages of the patients in each of the two groups by use of a *t* test showed that, on average, they were not significantly different. Calculation of exact probability showed that the distribution of males and females between the two groups of patients was random (P (double tail) = 0.67918). There was no significant difference between the average initial scores in the mental function tests or in average initial mean circulation times in the two groups.

The two groups of patients were therefore comparable initially.

Mental Function Tests

The analysis of the results of the mental function tests is set out in Table I. Analysis was made of the differences between the average initial scores and the average scores obtained after the first and the second treatment periods in each of the two groups, and the differences between the average scores on each occasion in the two groups. The scores obtained at the end of the first and the second periods were also compared with each other in order to show whether continuation of treatment for the second two months resulted in further significant change.

After the first two months group A patients obtained significantly higher average scores in the tests with the differences and picture absurdities (which were considered together), and with the pegboard. After four months significantly higher average scores were obtained in all the mental function tests except those with the paired associates and the building blocks.

TABLE I.—*Analysis of Results of Mental Function Tests*

	Group	Mean Test Score			Mean Test Score Differences			Standard Error of Mean Differences		
		I	II	III	I–II	II–III	I–III	I–II	II–III	I–III

I = Initial. II = After first treatment period. III = After second treatment period. * Significant result at $P < 0{\cdot}05$.

Group B patients showed no significant improvement in the average scores obtained in any of the mental function tests at the end of either treatment period.

Radiocirculograms

The positive and negative peaks of the rate of change of activity curve can be precisely defined in normal records. Where the circulation is greatly slowed, however, as it was in most of the patients studied, the rate of change of activity as the bolus leaves the cerebral circulation is small and the negative peak may be blurred or double (Fig. 2). To define this peak the curve has to be artificially smoothed, and this introduces a possible error of one to two seconds. The curves were read by us, by a third doctor (not associated with the trial), and by an architect without medical knowledge. The architect's method of smoothing the curves differed slightly from ours and his mean circulation times, in doubtful cases, were consistently a little longer, but the results in terms of improvement or worsening were the same in all cases.

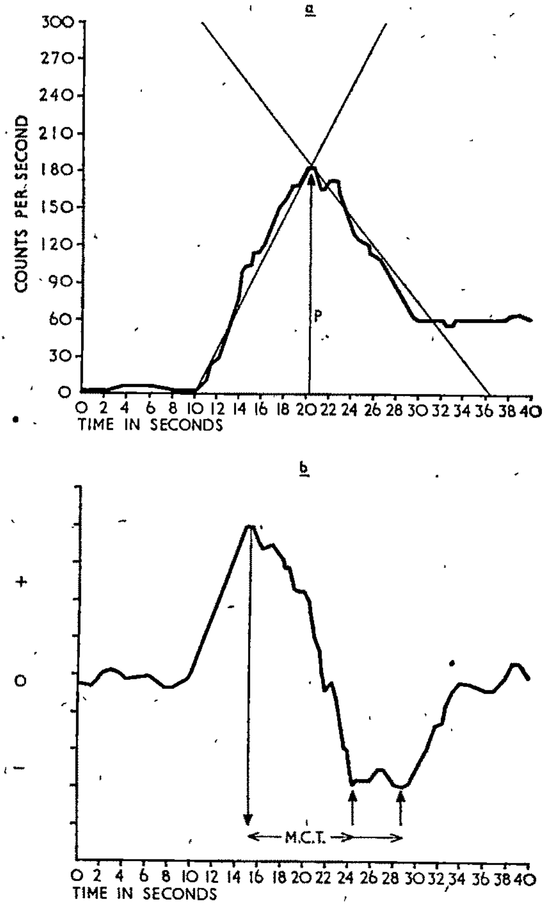

FIG. 2.—(*a*) Abnormal radiocirculogram. (*b*) Differentiated curve showing double negative peak.

The analysis of the results of the radiocirculograms is set out in Table II. Over the four-month period the average mean circulation time in group A patients decreased by 0.86 second (S.E. 0.39 second), and in group B patients there was an average increase of 0.55 second (S.E. 0.43 second). These average mean circulation-time changes are not significant. However, when the changes in group A are compared with those in group B, the average mean circulation-time difference 1.41 seconds (S.E. 0.58 second), is significant.

Correlation Between Mental Function Test Scores and Mean Circulation Times

Absolute values of cerebral blood flow can be derived from mean circulation times when the constants of proportion are known (Oldendorf, 1963). These constants depend on total blood volume and the ratio of brain blood volume to total blood volume, and therefore vary greatly from patient to patient.

If it is assumed that mental function test scores are related to cerebral blood flow, the constants of proportion would again be expected to vary greatly from patient to patient.

Two different kinds of constant, both of unknown value, are thus involved in the relation between mental function test scores and mean circulation times. In order to test for a relation by use of the figures obtained in the present trial, it was necessary to derive an expression in which the unknown constants did not appear.

The relation between mean circulation time in seconds (m) and cerebral blood flow in litres per minute (c) is

$$m = \frac{K}{c}$$

Where the constant K is dependent on total blood volume and the ratio of total blood volume to brain blood volume.

If mental function test score (x) is proportional to cerebral blood flow, then x=kc.

So that $$m = \frac{Kk}{x} \qquad \text{(I)}$$

As in any one patient Kk will be constant, m will vary inversely as x, and if m and x change then

$$m + dm = \frac{Kk}{x+dx} \qquad \text{(II)}$$

where dm represents the change in m and dx represents the change in x.

Subtracting (I) from (II)

$$dm = Kk\frac{-dx}{x(x+dx)}$$

and dividing by (I) to eliminate Kk

$$dm = \frac{-mdx}{x+dx}$$

A significant positive correlation between dm and the expression $-\frac{mdx}{x+dx}$ would support the hypothesis that mental function test scores vary with cerebral blood flow. Low correlation coefficients would suggest that the two are not related.

Correlation coefficients were calculated between changes in mean circulation time over the whole period of the trial and the changes in score in each separate section of the mental function tests as incorporated in the derived expression. In the calculations a few results had to be neglected because the numerator or the denominator of the expression became zero. None of the correlation coefficients so calculated was significant.

TABLE II.—*Analysis of Results of Radiocirculograms*

Group	Average Mean Circulation Times			Average Mean Circulation Time Differences			Standard Error of Mean Differences		
	I	II	III	I–II	II–III	I–III	I–II	II–III	I–III
A	12·64	11·96	11·77	−0·68	−0·18	−0·86	0·42	0·54	0·39
B	12·14	12·36	12·68	+0·23	+0·32	+0·55	0·39	0·51	0·43
A−B	+0·50	−0·40	−0·91	−0·91	−0·50	−1·41*	0·57	0·74	0·58

* Significant result at $P < 0{\cdot}05$.

Patients' and Ward Sisters' Opinions

Four of the patients on cyclandelate and three of those on placebo thought that the tablets had done them good.

The ward sisters were asked to say if the tablets had had any effect on the patient's general mental state. They thought that there had been no change in 18 of the patients, that 4 patients on placebo and 2 on cyclandelate had improved, and that none was made worse.

An examination made of all the patients who remained on treatment until the end of the trial showed that there had been no change in their general clinical condition.

Side-effects

Only one patient complained of any ill effect from the tablets, saying that they made her dizzy. She was persuaded to continue taking tablets, which later turned out to be placebo.

Discussion

The improvement which occurred in mental function in group A patients was not expected, and yet in the tests with the questions and in those described by Shapiro *et al.* (1956) the increase in the scores was highly significant ($P<0.001$).

The design of the trial ensured that bias on the part of the investigators, ward staff, or patients was removed; but the number of patients involved was small, and became smaller by the end of the four-month trial period. The assessment of improvement was made on the basis of an arbitrary scoring system, and the analysis of the score figures is made on the assumption that these are normally distributed. With such a small number of figures, however, it is not possible to validate or invalidate this assumption.

Nevertheless, as a significant improvement in mental function did occur in group A patients and not in group B patients, it must be concluded that the improvement was brought about by the action of cyclandelate.

The radiocirculogram results showed an average decrease in mean circulation time, indicating an average increase in cerebral blood flow only in group A patients. When the two groups were compared with each other the difference in the average mean circulation times over the four-month period was significant. It must be pointed out, however, that the change became significant only because group A showed a decrease in mean circulation time whereas group B showed an increase.

In patients with advanced arteriosclerosis, mean circulation times are prolonged and cerebral blood flow decreased (Nylin *et al.*, 1960). Parallelism has been found between decreased mental function and reduced cerebral blood flow (Schmidt, 1950).

A change in mean circulation time indicates a proportional change in cerebral blood flow, so that should changes in mental function test scores result from changes in cerebral blood flow correlation between mean circulation time differences and the expression relating them to mental function test score differences would be expected, but no such correlation was found.

Eichhorn (1962), in a study of patients with hypertensive encephalopathy, made the interesting observation, from detailed analysis of the rising slope of his blood-flow curves, that the improvement which occurred was in the precapillary (arteriolar) phase of the circulation. He concluded that improvement was caused by a more efficient distribution of the available blood rather than to an increase in total flow.

The improvement in mental function brought about by the action of cyclandelate may similarly result from a redistribution of, rather than a total increase in, cerebral blood flow.

It has been suggested that the decrease in cerebral blood flow encountered in elderly patients involves preponderantly those areas in which perfusion normally is relatively high (Sokoloff, 1960). Even minor increases in flow to such relatively ischaemic areas might well result in their improved function.

Summary

A controlled clinical trial is described in which the effect of prolonged administration of cyclandelate on mental function and cerebral flow in elderly patients was tested. Group A patients were given cyclandelate and group B patients were given a placebo, each for a period of four months.

A significant improvement in the results of mental function tests occurred only in group A patients.

An increase in the average cerebral blood flow occurred in group A patients and a decrease occurred in group B patients. Neither of these changes was itself significant, but when the two groups were compared with each other a significant difference occurred between them.

As there was no significant correlation between the changes in patients' scores in the mental function tests and changes in their mean circulation times, it is suggested that cyclandelate may bring about an improvement in mental function by producing a redistribution of blood flow within the cerebral circulation rather than an absolute increase in it.

We wish to thank Dr. J. D. Merrett for his help with the statistics; Mrs. E. T. Hutchinson and Mr. J. Coulter, who dispensed the tablets; Mr. Richard Wall, of Messrs. Brocades (Great Britain) Ltd., for supplies of cyclandelate and placebo and for much helpful criticism; and Miss M. Carey and Miss E. Johnston who prepared the manuscript.

Details of the mental function tests and of the scoring system used, together with individual test scores, mean circulation times, and their correlation coefficients, can be obtained on application to J. A. C. Ball.

Glossopharyngeal and Vagal Neuralgia

JAGDISH C. CHAWLA,* F.R.C.S.; MURRAY A. FALCONER,† M.CH. F.R.C.S.

Brit. med. J., 1967, 3, 529–531

Tic douloureux involving the glossopharyngeal nerve is rare and when it does occur probably often involves the vagus nerve as well. Many cases are undoubtedly not recognized, and yet the condition responds favourably and permanently to intracranial section of the glossopharyngeal nerve and upper filaments of the vagus nerve. We therefore propose to review the literature, discuss our own experiences, and try to clarify the clinical syndromes that this condition presents and the surgical approach that is required.

Review of the Literature

The condition of glossopharyngeal neuralgia was first described by Weisenburg (1910), who recognized it in a patient with a tumour of the cerebellopontine angle. In most cases, however, there is no known pathological condition. Harris (1926) described it as the idiopathic glossopharyngeal neuralgia. The usual description is of paroxysms of pain of a stabbing or lancinating character located in the base of the tongue and faucial region on one side, and provoked by swallowing, talking, and coughing. When the pain is severe the patient may not even be able to swallow his own spittle. Bouts of recurrent pain may last a few minutes, hours, or even days at a time, each individual stab, however, being momentary. The majority of patients are elderly, and in our series of 10 cases the ages ranged from 32 to 77 (average 62.6 years). Males are more often affected than females (9 to 1 in our series). Similar observations were made by Dandy (1927), but Bohm and Strang (1962) reported an equal occurrence in the sexes. As time goes by, however, recurrent bouts of pain tend to become more frequent and the periods of remission shorter.

One of the largest series so far reported is that of Bohm and Strang (1962), who made the point that the pain could radiate in other directions, notably into the vagal territory. This has been our experience also. Quite often the stabs of pain are felt deep in the external meatus of the ear and beneath the angle of the jaw, and sometimes even deeply in front of or behind the external auditory meatus. In some cases it may reach the tragus of the ear (with a trigger area there), but the main site of the pain is deep. When this occurs differential diagnosis from atypical forms of third-division tic douloureux becomes difficult (see below).

The surgical treatment reflects these difficulties in diagnosis as well as the efficacy of the various surgical approaches. There are three approaches, which may be described as cervical, tonsillar, and intracranial. The first successful approach was that of Sicard and Robineau (1920), who carried out a dissection of the glossopharyngeal nerve and pharyngeal branch of the vagus nerve in the neck and avulsed them. Harris (1926) was uncertain of the involvement of the vagus nerve and wondered whether section of the pharyngeal branch of the vagus nerve was necessary. Dandy (1927) also at first suggested that the vagus nerve is not implicated, and later advocated the intracranial approach with section of the upper filaments of the vagus nerve in addition to the glossopharyngeal nerve (Dandy, 1945). Adson, in 1925, was the first to use this approach, but his intervention was first reported by Love (1944). Dandy (1945) did record two cases in which, after intracranial section of the glossopharyngeal nerve alone, pain persisted, but it disappeared after a second operation in which the upper vagal rootlets were cut, an experience which Bohm and Strang (1962) also shared. Wilson and McAlpine (1946) reported a single case in which the glossopharyngeal nerve had been dissected in its tonsillar bed and avulsed with relief. Our experience, however, suggests that recurrence can arise after this procedure, and has led us to recommend intracranial section of the glossopharyngeal nerve plus section of the upper two vagal rootlets.

Present Series

This study is based on a review of 10 patients admitted to this unit for treatment of glossopharyngeal neuralgia, with reference to type of pain, its aggravating factors, surgical treatment, and other relevant observations (see Table).

Duration and Type of Pain

The length of history varied from 15 months to 15 years. The pain was paroxysmal, and was described as lancinating or lightning-like jabs. The paroxysms occurred in characteristic bouts lasting from a few seconds to two minutes. Dandy (1927) wrote that the pain rarely lasted over a minute. In one of our cases, however, some bouts lasted up to five minutes, and paroxysms of pain continued to occur at frequent intervals throughout the day over a period of a few days to a few weeks before a spontaneous period of remission ensued. The pain is very severe, and in Case 3 the paroxysms occurred so often that section of the glossopharyngeal nerve was performed as an emergency to enable the patient to swallow. The period of remission before operation was also variable in this series: the longest was four years (Cases 1 and 4). Adson (1924) reported a remission of three years and nine months. One observation which stands out in this series is that the periods of remission become shorter with ensuing attacks, but an identical pain always returns in the same area of distribution.

The location and distribution of pain in this series was always unilateral, and was as follows (see Table): back of tongue (Cases 9 and 10), fauces (Cases 3 and 10), tonsillar region (Case 7), deep in the ear (Cases 1, 2, 5, and 6), in front of or behind the ear (Cases 2 and 5), deep to the angle of the jaw (Cases 3, 5, 6, and 8), deep in the upper side of the neck (Cases 1, 4, and 8), and deep in the throat (Cases 1 and 2). Only one patient (Case 9) had pain confined to the back of the tongue with no radiation.

Aggravating Factors

The commonest method of precipitating attacks of the pain was swallowing, but attacks were also induced in other ways, such as coughing, sneezing, talking, touching the tragus of the ear, turning the head towards the side of pain, and rolling towards the site of pain.

In only one patient (Case 4) was there a trigger zone. His pain was brought about by touching the tragus on the painful side, but in three other patients the tragus was also sensitive.

† Director, Guy's-Maudsley Neurosurgical Unit, London S.E.5.

Other Observations

There was no seasonal influence on the symptomatology, except in one patient (Case 1) who had pain only in winter. One patient (Case 2) had vertigo without tinnitus or deafness. Bohm and Strang (1962) reported two similar cases. None of our patients had any sensory impairment in the area of the distribution of pain. All were symptom-free in between attacks of pain, apart from one patient (Case 1) who complained of a hot, flushed feeling in the affected area between the bouts of pain. Our follow-up periods (excluding one patient (Case 7) who died postoperatively) have ranged from four and a half weeks to six years, and all patients appear to have been relieved during that time.

Treatment

Seven out of the ten patients were treated by section of the glossopharyngeal nerve and the upper rootlets of the vagus nerve, and two by section of the glossopharyngeal nerve alone. One patient (Case 10) was pain-free on admission, but was admitted later to another neurosurgical unit with recurrent pain. He was operated on and remained free from pain until he committeed suicide because of depression. The postoperative death, on the 11th day, on a 77-year-old patient, was due to intestinal obstruction (Case 7). Seven out of the remaining eight patients with an adequate follow-up have remained pain-free. The eighth patient (Case 9) originally had pain in the back of the tongue on one side, and after operation was free of pain for four months. Pain then occurred in the lower jaw. He was treated by alcohol injection of the trigeminal ganglion and has since remained pain-free. It is possible that he had both glossopharyngeal and trigeminal neuralgia. Bohm and Strang (1962) described a similar case in which second division trigeminal neuralgia occurred five years after a glossopharyngeal section.

Postoperative Course

Only one patient (Case 4) had transient difficulty in swallowing. Six patients showed detectable sensory depression in the oropharynx, the faucial region, the posterior third of the tongue, and the adjacent half of the soft palate. Two patients had sensory depression in the concha, one of them having had no sensory depression in the oropharynx. In one case no mention of any sensory loss was recorded. Another patient (Case 3) developed transient auricular flutter after he had undergone glossopharyngeal section with the upper rootlets of the vagus.

Discussion

Compared with trigeminal neuralgia, glossopharyngeal neuralgia is relatively rare. Bohm and Strang (1962) showed an incidence of 1% in Olivecrona's material, and Harris (1937) an incidence of 0.57%. The corresponding figure for this neurosurgical unit is 0.75%.

The presence of a trigger zone is a rare finding, though there may be areas tender and sensitive to touch. One case in our series involved the tragus (Case 4). Harris (1926) remarked on the absence of trigger zones and thought it to be the main difference between glossopharyngeal and trigeminal neuralgia. However, cases with a trigger zone in the faucial region have been described (Dandy, 1927).

The location, distribution, and radiation of pain lie in the area of sensory supply of the glossopharyngeal nerve and of the auricular and pharyngeal branches of the vagus nerve—i.e., propharynx, concha of the ear, and deep to the angle of the jaw. Dandy (1927) implicated Jacobson's nerve in the radiation of pain to the ear, and described the radiation of pain to the angle of the jaw and concha as referred. Keith (1932) described pain in the regions of the upper part of the neck, the angle of the jaw, and the cheek, nose, and eyes, and regarded them as overflow phenomena. We think that pain deep to the angle of

Salient Features of Cases in Chronological Order

the jaw, upper cervical region, and concha is due to involvement of the auricular branch of the vagus nerve. We did not observe overflow to the cheek, nose, or eyes. Bohm and Strang (1962) subdivided their series into two groups—oropharyngeal and aural—according to the main symptomatology, but patients usually present with pain in both zones concurrently. Typically there is no sensory impairment in the area of pain, as there usually is when tumours of the cerebellopontine angle or base of the skull are present.

The clinical picture of "idiopathic glossopharyngeal neuralgia" is so characteristic that diagnosis is seldom difficult. Glossopharyngeal neuralgia, however, may be confused with trigeminal neuralgia in patients with pain in the region of the tragus or deep to the angle of the jaw.

There is some evidence that glossopharyngeal neuralgia may be controlled by medication—for example, vitamin B complex, Tegretol (carbamazepine)—but no proof that the relief is lasting. Treatment of this neuralgia is essentially surgical. It has passed through various stages from dissection and avulsion of the glossopharyngeal nerve and pharyngeal branch of the vagus nerve in the neck to the intracranial section of the glossopharyngeal nerve alone or combined with the upper two rootlets of the vagus nerve. However, the avulsion of nerves in the neck has often been followed by recurrence of pain over a period of time—for example, Case 1—as has avulsion in the tonsillar fossa (Case 7). The treatment of choice remains the intracranial section of the glossopharyngeal nerve and upper two rootlets of the vagus nerve, as we feel that the latter nerve is also implicated. In skilled hands this operation carries a negligible mortality and can be performed on elderly patients.

Surgical Approach

This is essentially the approach by Dandy (1927), though nowadays it is facilitated by operating on the patient in the upright position. The legs should also be raised or bandaged in elderly patients to prevent postural arterial hypotension. The procedure is carried out through a small suboccipital craniectomy under endotracheal anaesthesia. Enough bone is removed to expose the lateral sinus above and the sigmoid sinus laterally—that is, about 3–4 cm. diameter. The dura is opened, with a small flap swung laterally over the sigmoid sinus. The cerebellopontine angle is opened up after the posterior fossa has been slackened either by slipping a retractor over the cerebellar hemisphere and opening the cisterna magna or by releasing a previously placed lumbar puncture needle. The rootlets of the ninth, tenth, and eleventh cranial nerves are seen arranged in a vertical column from above down. The ninth cranial nerve is a single filament normally separated from the multiple filaments of the tenth nerve by a dural isthmus as the nerves pass out through the jugular foramen. The ninth cranial nerve is hooked up and sectioned at this position, followed by section of the upper two rootlets of the vagus. In closing the craniectomy the dura is sutured back into position. The patient is usually sitting out of bed on the first day, and relieved of pain from the time of operation.

Summary

Ten cases of glossopharyngeal neuralgia have been studied and the literature has been reviewed. A more correct classification would be to describe the condition as "glossopharyngeal and vagal neuralgia." Evidence is given to support this view. Intracranial section of the glossopharyngeal nerve and the upper two rootlets of the vagus nerve is the operation of choice.

We wish to thank Mr. P. H. Schurr and Mr. J. J. Maccabe for permission to include their cases, and also our various neurological colleagues, particularly Dr. M. J. McArdle, for entrusting us with patients under their care.

Brit. med. J., 1967, **3**, 531–533

A haemoglobin variant is the result of an amino-acid substitution in one of the two pairs of polypeptide chains which constitute the haemoglobin molecule. Foetal haemoglobin (Haemoglobin F) has a pair of α-chains and a pair of γ-chains, and is denoted as $\alpha_2\gamma_2$. Variants of Haemoglobin F may thus be divided into two groups, those with abnormal α-chains and those with abnormal γ-chains.

An α-chain substitution gives rise not only to a variant of Haemoglobin F, but also to a variant of Haemoglobin A ($\alpha_2\beta_2$) and a variant of Haemoglobin A_2 ($\alpha_2\delta_2$) in the same individual. A γ-chain substitution, in contrast, can give rise only to a variant of Haemoglobin F. In the same way a β-chain substitution can give rise only to a variant of Haemoglobin A; most of the common haemoglobin variants—for example, Haemoglobins S, C, D, and E—are β-chain variants.

Few γ-chain variants have been described, and in only one case, that of Haemoglobin F Texas I, has the amino-acid substitution been identified (Schneider and Jones, 1965; Jenkins, Beale, Black, Huntsman, and Lehmann, 1967). We here describe a new γ-chain variant and define its amino-acid substitution. The variant, which is designated Haemoglobin F Hull, was first found as an electrophoretically slow component of the cord-blood haemoglobin of a normal baby of native English stock (Fig. 1). It made up 14% of the total haemoglobin, determined by the method of Marengo-Rowe (1965). It was found again in the cord blood of a subsequent baby born to the same parents, comprising 9% of the total haemoglobin. This baby was born after 30 weeks of gestation and died of prematurity after a few days. A third example of the variant was found in a healthy baby born to parents who are, so far as is known, unrelated to the first family, though both families live in the same town (Kingston-upon-Hull). The variant comprised 7% of the cord-blood haemoglobin of this baby. Although twice found in Hull families, the variant has not been observed again during a survey of 12,000 cord bloods in Britain.

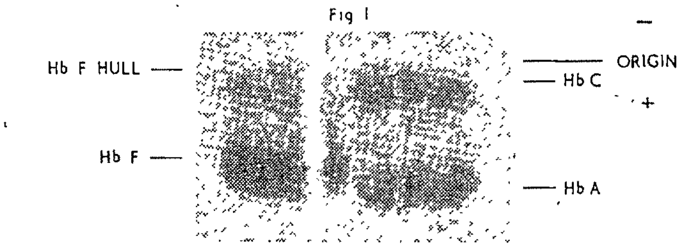
† Medical Research Council Abnormal Haemoglobin Research Unit, University Department of Biochemistry, Cambridge.
‡ St. Thomas's Hospital Medical School, London S.E.1.



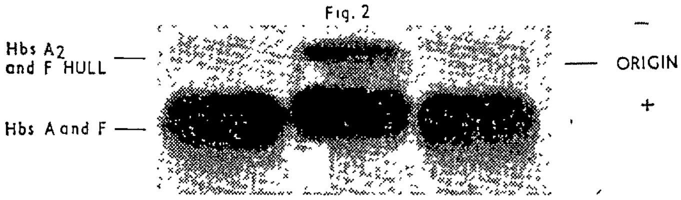


FIG. 1.—Haemoglobin electrophoresis on paper at *p*H 8.9 (barbiturate buffer). Left: cord blood containing Haemoglobin F Hull. Right: adult heterozygous for Haemoglobin C.

FIG. 2.—Haemoglobin electrophoresis on paper at *p*H 8.9 (tris buffer). Centre: cord blood containing Haemoglobin F Hull (near origin). Left and right; blood from the parents of this infant; Haemoglobin A_2 is shown near origin. The electrophoretic mobilities of Haemoglobins A_2 and F Hull are similar.

The abnormal haemoglobin was thought to be a variant of Haemoglobin F for the following reasons:

(1) It was absent from the blood of the parents (Fig. 2) in both families. An examination of the antigens of nine blood group systems in parents and children failed to provide evidence of aberrant paternity in any of the three cases.

(2) The ultraviolet spectrum of the isolated variant haemoglobin showed a clearly resolved tryptophan fine structure band at 289 mμ (Fig. 3). This is a characteristic feature of Haemoglobin F and its γ-chain variants.

(3) The amount of the variant present in the blood of the two surviving infants declined during the first few months of life.

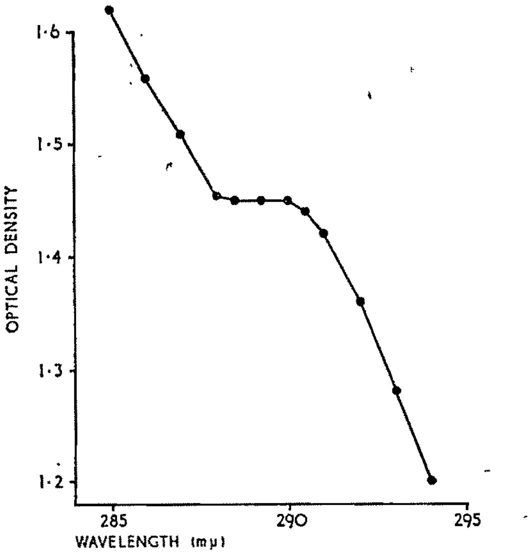

FIG. 3.—Ultraviolet spectrum of the isolated haemoglobin variant, showing the tryptophan fine structure band.

On paper electrophoresis at *p*H 8.9 Haemoglobin F Hull moved slightly more slowly towards the anode than Haemoglobin C (Fig. 1). The distance between the variant and Haemoglobin F was approximately the same as that between Haemoglobin C and A. If this difference in mobility is due to a single mutation it can be assumed that, as in Haemoglobin C, a positively charged amino-acid residue has taken the place of a negatively charged residue in each of the two abnormal polypeptide chains. The nature of the genetic code (Nirenberg *et al.*, 1965) is such that a charge change of this type is due to a substitution of glutamic acid by lysine (Beale and Lehmann, 1965).

In order to define the amino-acid substitution more fully, the haemoglobin was converted to globin, and peptide maps ("fingerprints") were prepared according to the procedures of Ingram (1958) and Baglioni (1961); these procedures have been described in detail by Beale (1966). Fingerprints of pure Haemoglobin F, isolated from normal cord blood by chromatography at pH 6 according to Huisman and Prins (1955), were prepared simultaneously with those of the variant.

Fingerprints of the variant when compared with those of Haemoglobin F (Fig. 4 A and B) showed that the spot corresponding to the thirteenth tryptic peptide of the γ-chain (peptide γTpXIII), marked 1 in Fig. 4 A and B, was absent in the variant. This peptide (γTpXIII) contains residues 121–132 of the 146 composing the γ-chain. Number 121, the first in this sequence, is a glutamic acid residue. Two abnormal peptide spots, which are marked 2 and 3 in Fig. 4, had appeared. Peptide 2 is positively charged, while peptide 3 is neutral. The abnormal peptides were eluted with constant-boiling HCl and analysed for their amino-acids (Spackman, Stein, and Moore, 1958). The results are shown in Table I. The abnormal positively charged peptide contains one extra lysine and one glutamic acid residue less when

Total ..		12		11

TABLE II.—*Amino-acid Sequences of the Two Abnormal Peptides in the Fingerprints of Haemoglobin F Hull, Compared with the Normal Peptide γTpXIII of Haemoglobin F According to Schroeder, Shelton, Shelton, Cormick, and Jones (1963)*

γTpXIII	121 glu —	122 phe —	123 thr —	124 pro —	125 glu —	126 val —	127 gln —	128 ala —	129 ser —	130 trp —	131 gln —	132 lys
Peptide 2 (positively charged)	121 lys —	122 phe —	123 thr —	124 pro —	125 glu —	126 val —	127 gln —	128 ala —	129 ser —	130 trp —	131 gln —	132 lys
Peptide 3 (neutral)		122 phe —	123 thr —	124 pro —	125 glu —	126 val —	127 gln —	128 ala —	129 ser —	130 trp —	131 gln —	132 lys

compared with the peptide γTpXIII (Table II). This indicates that a glutamic acid→lysine substitution has occurred. The abnormal neutral peptide has one glutamic acid residue less than γ TpXIII. This can only be explained by a glutamic acid→lysine substitution at position 121 in the γ-chain. The presence of two abnormal peptides in place of γTpXIII indicates that tryptic digestion results in partial cleavage only between residues 121 and 122 of the variant haemoglobin.

Baglioni and Lehmann (1962) described two types of Haemoglobin O which they designated O Arab and O Indonesia. Haemoglobin O Arab bears a glutamic acid→lysine substitution at position 121 in the β-chain, while Haemoglobin O Indonesia bears a glutamic acid→lysine substitution at position 116 in the α-chain.

In a model of the haemoglobin molecule (Perutz, 1965) each polypeptide chain is divided into segments denoted by letters. The eight helical regions are lettered from A nearest the amino end to H nearest the carboxyl end, while the interhelical regions are lettered according to the adjoining helical regions—that is, AB, BC, CD, etc. The residues within each region are given numbers from 1 to n. By this notation the residues α116, β121, and γ121 are homologous, all three being designated GH4. Haemoglobins O Arab, O Indonesia, and F Hull are therefore variants of haemoglobin which bear identical substitutions at homologous positions in different polypeptide chains of human haemoglobin.

This is the first example of such a situation, and its interpretation is uncertain. It is possible that mutations affecting this position are unusually common; indeed, another haemoglobin variant, Haemoglobin D Punjab, has a glutamic acid→glutamine substitution at position 121 in the β-chain (Baglioni, 1962).

Summary

An identical variant of foetal haemoglobin was found in two unrelated families in Hull. It has not been seen again in a survey of 12,000 cord bloods in Britain. Haemoglobin F Hull differs from Haemoglobin F ($\alpha_2\gamma_2$) by the substitution of lysine for glutamic acid in position 121 of the 146 amino acid residues of the γ-chain. The same substitution occurs in the homologous position in the α- and β-chains of human haemoglobin, giving rise to Haemoglobins O Indonesia and O Arab respectively. The addition of glutamine in this position of the β-chain characterizes the common variant Haemoglobin D Punjab.

We are grateful to Mr. D. Irvine, Miss M. Joyce, and Miss P. M. Kynoch for technical assistance. Two of us (R. G. H. and A. J. B.) thank the Endowment Fund of St. Thomas's Hospital for financial support.

We gratefully acknowledge the co-operation of the nursing staff, obstetricians, and pathologists of the following hospitals who have sent us cord-blood samples: Copthorne Hospital, Shrewsbury; Coventry and Warwickshire Hospital; Dulwich Hospital, London; Guy's Hospital, London; General Lying-in Hospital, London; Hull Maternity Services; Lambeth Hospital, London; Lewisham Hospital, London; North Middlesex Hospital, Edmonton; Oldchurch Hospital, Romford; Plaistow Maternity Hospital; Queen Mary's Maternity Hospital, Hampstead; Royal Free Hospital, London; St. Alfege's Hospital, Greenwich; St. Andrew's Hospital, Bow; St. Bartholomew's Hospital, London; St. Thomas's Hospital, London; The Lister Hospital, Hitchin; The London Hospital, London; Victoria Maternity Hospital, Barnet; Waltham Maternity Hospital; Westminster Hospital, London; Wexham Park Hospital, Slough; Windlesham Maternity Hospital; Woking Maternity Hospital.

Paraplegia Caused by Spinal Metastasis from Thyroid Cancer*

K. E. HALNAN,† M.D., M.R.C.P., F.F.R.; P. H. ROBERTS,‡ F.R.C.S.

Brit. med. J., 1967, 3, 534–536

Paraplegia caused by metastases in the spine is a common and unfortunate incident in the natural history of many types of cancer. Even when the site of the primary tumour is known, treatment is too often symptomatic only, and when the primary is not known it is sometimes thought that energetic pursuit of the diagnosis is academic, and that the patient is better left to "die in peace." However, valuable time can also be wasted on extensive and sometimes fruitless searches for the primary tumour only to find that by this time the paraplegia is irreversible.

The striking complete success of treatment of a recent case of thyroid cancer, undiagnosed until eight months after the onset of spinal cord compression and two months after complete paraplegia, has prompted a review of nine cases seen at the Christie Hospital, Manchester, collected from about 700 new cases seen between 1945 and 1965.

Clinical Material

All but one (Case 9) of the patients had a history of thyroid disease, and in three (Cases 1, 4, and 5) thyroidectomy had been performed between three and nine years before in the belief that the lesion was benign (Table I). In these three cases, at least, it would seem that either dissemination or growth of metastases must have been very slow.

The presenting symptoms in four cases were related to the thyroid gland or neck and in the remainder to the spine. In only three cases was there a definite interval between the diagnosis of the primary tumour and the first signs of cord compression, this being three months and three and six years. However, in retrospect, if it is assumed that the apparently benign lesion had been malignant at the time of thyroidectomy, then the intervals between the appearance of the primary and the development of the spinal cord signs extend to three, six, and thirteen years.

In the seven cases for which full details are available paraplegia followed the first signs of compression in an average time of nine months and in all but one the paraplegia was complete (Table II). In the four cases showing recovery (Cases 1, 6, 8, and 9) the duration of the paraplegia was two months, two months, one month, and three weeks.

Full recovery was thought to have occurred when the patient had regained full bladder and bowel control and could walk without any external support.

Treatment of the paraplegia was by decompression in five cases (Nos. 1, 4, 6, 8, and 9), and in two of these the biopsy obtained was diagnostic (Cases 1 and 9). In three (Cases 2, 3, and 7) paraplegia was a terminal event and no attempt was made to decompress the cord. In the remaining case (No. 5) the biopsy was diagnostic, and, though some improvement followed treatment, death occurred six months later. Postmortem examination showed evidence of transverse myelitis at the level of the lesion which may have been due to irradiation.

TABLE I

Case No.	Age and Sex	Previous Thyroid History	First Signs of Malignancy	Time of Development of Spinal Signs from Diagnosis of Malignancy
1	51 M	Thyroidectomy 3 years before for "benign goitre"	Weakness of legs	0
2	70 F	Lifelong goitre. No treatment	Cervical lymph node metastases	3 months
3	55 M	Malignant goitre with cervical node metastases	Swelling in thyroid with cervical node metastases	Not known
4	54 M	"Benign" thyroidectomy 9 years before	Recurrent swelling of thyroid and metastasis. ileum	6 years
5	47 M	"Benign" thyroidectomy 6 years before	Pain and weakness in arm from spinal metastases	0
6	47 F	Swelling thyroid for 10 years	Weakness of legs, pain in neck, and paraesthesiae in arms	0
7	64 F	Goitre for 25 years, increased swelling for 5 years	Swelling in neck	Probably 4 years
8	54 M	Neck swelling for 2 years	Backache	0
9	66 F	None	Backache and sciatica	0

Abstracts of two cases are given.

Case 1

A 51-year-old man presented in January 1964 with a two-months history of weakness and numbness of the legs and urgency and increased frequency of micturition. A thyroidectomy had been performed in 1961 for a retrosternal goitre suggested histologically to be benign.

He was paraparetic with a sensory level at the sixth dorsal spinal segment. Radiographs showed a destructive lesion involving the

sixth dorsal vertebra. No swelling was palpable in the neck and investigations failed to reveal a primary tumour.

He was admitted to hospital in August 1964, having been totally paraplegic for two months and unmanageable at home. Radiographs showed little change in the spine but a further metastasis in the ilium.

On 7 August a transthoracic anterior decompression of the spine was performed and the biopsy obtained showed a well-differentiated thyroid metastatic carcinoma. Radioiodine studies showed a 40% uptake in the neck and 9% in the region of the spinal metastasis. On 17 August 150 mCi of iodine-131 was given. By 30 August some movement had returned to the legs; he was walking between bars on 9 September and by 5 October with the aid of tripods only.

On 14 October tracer studies showed 2% uptake in the neck, 10% in the ilium, and 6% in the spine. A further dose of 200 mCi iodine-131 was given together with 4MV *x*-ray treatment of 1,500 rads skin dose each to the spine and the ilium. He was given 0.3 mg. sodium L-thyroxine daily by mouth from this time.

Rapid improvement continued so that by January 1965 he was able to walk a quarter of a mile (400 metres), ride a bicycle, and was laying concrete slabs in his garden. Bladder and bowel control was normal. Full motor power had returned to the legs. In February 1965 (after temporary cessation of thyroxine) 200 mCi iodine-131 was given, and in May radiographs showed regression and sclerosis of the spinal lesion.

He returned to work in August, and when last reviewed in May 1966 was completely well continuing the maintenance dose of thyroxine.

Case 6

A 47-year-old woman was admitted in July 1962 with a spastic paraplegia, having complained of weakness of the legs for 12 months and of a small goitre for 10 years.

At laminectomy a tumour was found in the seventh cervical and first thoracic vertebrae; histologically it was a poorly differentiated follicular thyroid cancer. During August four MV *x*-ray therapy of 3,000 rads skin dosage was given to the lesion over three weeks. By September there had been considerable return of power to the legs, and by January 1965 this was complete, together with normal bladder and bowel function.

In March 1965 the thyroid was ablated by 150 mCi iodine-131, followed two months later by a further 150 mCi. Maintenance therapy of 0.3 mg. sodium L-thyroxine daily was started.

In January 1966 the patient was completely well with normal gait and bladder and bowel function.

Cases Collected from the Literature

A search of the literature has produced histories of only four cases of paraplegia due to thyroid spinal metastases. Bradley Coley (1949) reported a case developing paraplegia 23 years after thyroidectomy for a "benign lesion" and 11 years after metastases had appeared. Full return of function followed decompression and *x*-ray treatment and the patient remained well for eight years. Outerbridge (1947) reported two cases. In one the paraplegia developed slowly over two years and recovery was only partial after decompression and *x*-ray therapy. In the other the onset was rapid, but the paraplegia was incomplete and complete recovery followed laminectomy and *x*-ray treatment. Barron, Hirano, Araki, and Terry (1959) reported a case of paraplegia of rapid onset showing complete recovery after decompression. Death occurred nine months later from widespread metastases.

Discussion and Review of Literature

Cancer of the thyroid is a rare disease, approximately 12 cases occurring per million population per year and accounting for 0.1% of all deaths from malignancy.

Metastatic spread from an apparently benign lesion of the thyroid was first described in 1876 by Cohnheim as "benign metastasizing goitre." Malignant change may not be apparent clinically and may not be recognized on histological examination. This occurred in three of our patients (Cases 1, 4, and 5) and in one of these the failure to recognize the possibility of malignant change resulted in an extensive and fruitless search for a primary tumour. The incidence of malignant change in non-toxic nodular goitre in three large series of cases was 7.6% (Hinton and Lord, 1945), 7.8% (Surridge and Kroger, 1961), and 8.5% (Fowler, Majarakis, and Cole, 1961).

Though spread to bone, in particular the vertebrae, is common in thyroid cancer (Halnan, 1965), the primary tumour itself is so uncommon that spinal metastases from the thyroid are rare in comparison with those from the bronchus, breast, and gastrointestinal tract. Reviewing metastases to the spine, Arseni, Simionescu, and Horwath (1959) found only two from the thyroid among 231 cases; Barron *et al.* (1959) found three among 127; Toumey (1943) two among 95; Alexander, Davis, and Field (1956) one among 15; Mullan and Evans (1957) one among 50; and Brice and McKissock (1965) none among 160. Collectively these series give an incidence of thyroid metastases causing paraplegia of about 1%.

Botterell and FitzGerald (1959) commented on the remarkably constant presentation of spinal metastases with local back pain sometimes together with nerve-root pain. This has been confirmed by Brice and McKissock (1965) in 90% of their cases, by Barron *et al.* (1959) in 82%, and by Arseni *et al.* (1959) in 86%. Back pain alone occurred in three of our cases, with leg pain in one, but in two others weakness of the legs alone was present.

The progress from the first signs of cord compression to paraplegia varies according to the source of the metastasis. Kennady and Stern (1962) found that in bronchogenic metastases the average time from local compression to paraplegia was four weeks, while in those from the breast it was 14 weeks. Prognosis is related to the rate of progress; the more rapid the rate the worse the prognosis. In our cases the progress was very slow, in two cases extending over a year and in two further cases between six months and one year.

Difficulty in diagnosis may occur when no evidence of bony destruction is seen on the radiographs, as occurred in 12% of the cases of Barron *et al.* (1959) and 10% of those of Brice and McKissock (1965). However, in thyroid cancer in all our cases and in those collected from the literature radiological bone changes were seen, and this may be related to the slow rate of growth. In thyroid metastases uptake of radioiodine is diagnostic but its absence is by no means exclusive. In 18% of cases extensive searches may fail to demonstrate a primary tumour (Arseni *et al.*, 1959).

Treatment should be by immediate decompression of the spinal cord, and if the primary tumour is unknown a biopsy will provide the diagnosis. Decompression is most commonly by laminectomy, but an anterior approach may often be better and leave the spine more stable.

The results of decompression of the spine in general are disappointing. Of 21 cases operated on by Mullen and Evans (1957) there were only two good results and one of these was from the thyroid. Arseni *et al.* (1959) noted improvement in 29% and complete recovery in 7.8% of cases; this series did not include any from the thyroid. Kennady and Stern (1962) noted worth-while improvement in sphincter control in 19 out of 59 cases. Brice and McKissock (1965) reported improvement in 30%.

In our series three cases were terminal, but of the remaining six complete recovery of the spinal cord lesion occurred in four (Cases 1, 6, 8, and 9) (Table III). In two cases recovery occurred in spite of the presence of paraplegia for two months. Full recovery has been maintained in two cases (Nos. 1 and 6) for 22 months and three and a half years after decompression.

In Case 8 the improvement has so far continued for six months after decompression. In Case 9 the paraplegia recurred four years later but there are now multiple metastases.

TABLE III

Case No.	Outcome	Length of Follow-up
1	Complete recovery	22 months
2	Death	
3	"	
4	Improvement following laminectomy for 2 years, when further metastases caused return of paraplegia, which was terminal	
5	Death probably due to radiation myelitis and not metastases. Temporary and partial improvement	
6	Complete recovery	3½ years
7	Death due to terminal quadriplegia	
8	Complete recovery	6 months
9	Complete recovery, but later on signs of further cervical cord compression were developing	4 years

The prognosis of thyroid cancer, particularly when well differentiated, may be surprisingly good, especially in the younger age groups (Halnan, 1966). Thus the presence of distant metastases may not be a terminal event even when paraplegia occurs, unless the latter itself is allowed to lead to death. Furthermore, bone metastases characteristically occur from follicular cancer with good uptake of radioiodine, as in all our cases that recovered. An optimistic and energetic approach seems justified in this type of case, quite different from the management of a patient with rapidly growing multiple metastases from undifferentiated carcinoma, whether originating in the thyroid or elsewhere.

Conclusions and Summary

Thyroid carcinoma is rare, but commonly metastasizes to bone, the well-differentiated variety sometimes spreading exclusively to bone.

Cases of paraplegia due to thyroid metastases are rare and few have been reported in the literature.

Metastasis to the spine causing cord compression should be treated as an emergency procedure and attempts to find the primary tumour should not delay this, particularly since in some cases no primary tumour may be found.

A thyroid tumour should always be considered as a possible origin of spinal metastases, and a history of thyroidectomy (even though apparently for benign disease) should add to rather than remove suspicion.

Though the results of surgical decompression for spinal metastases are often poor this should not rule out operation, since, even though life may not be prolonged, relief of the paraplegia is of considerable benefit. After thyroid metastases the extent and duration of recovery are significantly better than after most other tumours.

The duration of the paraplegia should not contraindicate operation. With thyroid metastases full recovery may occur even when two months have elapsed.

The first local treatment should be surgical, but this must be followed by treatment to both the primary and the secondary tumours; thyroidectomy is sometimes appropriate, but either or both radioiodine and *x*-ray therapy are almost always needed.

We are grateful to all colleagues at the Christie Hospital and elsewhere who have assisted in the care of these patients.

Medical Memoranda

Need for Clarity in Infant Feeding Instructions

Brit. med. J., 1967, **3**, 536–537

The danger of hypernatraemia occurring as a result of accidental salt-poisoning or excessive administration of solute is well recognized in infancy (Finberg and Harrison, 1955). The present report describes two cases admitted to the Royal Hospital for Sick Children, Edinburgh, within the past year with hypernatraemic dehydration resulting from parental failure to interpret correctly the manufacturers' instructions for reconstituting dried-milk formulae.

CASE 1

A 4-week-old male infant was admitted to hospital in January 1966 with a two-day history of irritability, refusal of feeds, and a high-pitched cry. He had been born in hospital at full term. This was the mother's first pregnancy and was uncomplicated. His birth weight was 4 kg. (8.8 lb.). There were no immediate neonatal problems, but on discharge from hospital on the fifth day of life his feeding was changed from half-cream milk to Ostermilk No. 2, reconstituted as follows: 6 measures dried-milk powder+3 tablespoonfuls water+1 teaspoonful of sugar, four-hourly. Despite the paste-like consistence of this mixture he had accepted feeds until two days before admission to hospital. When admitted he was dehydrated, with early peripheral circulatory failure. His cry was high-pitched and feeble. Neurologically he was generally hypertonic, with neck retraction, twitching of the eyelids, vertical nystagmus, and tremor of the limbs. His abdominal wall was doughy in consistency. Examination showed nothing else of note. Initial electrolyte values were—sodium 207 mEq/l., potassium 7.5 mEq/l., chloride 165 mEq/l., and calcium 7.2 mEq/l. His *p*H was 7.08, P_{CO_2} 71 mm. Hg, and standard bicarbonate 15.8 mEq/l. The blood urea nitrogen was 250 mg./100 ml.

He was treated as recommended by Harrison and Finberg (1964), being gradually rehydrated with a solution containing 20 mEq sodium per litre. Over the next three days he had repeated convulsive episodes, but gradually the serum electrolytes and blood urea nitrogen levels returned to normal. His subsequent progress has not been satisfactory and he is now severely handicapped mentally.

CASE 2

This 4-week-old female infant was admitted to hospital in October 1966, with symptoms and clinical features identical to those in

Case 1. She was the tenth-born in her family and weighed 2.75 kg. (6 lb.) at birth. She also was fed on Ostermilk No. 2, reconstituted as follows: 2½ measures Ostermilk No. 2+3½ *measures* water+ 1 teaspoonful of sugar, four-hourly. Her initial sodium level was 194 mEq/l., potassium 7.1 mEq/l., and chloride 156 mEq/l. The carbon dioxide combining power was 17 mEq/l., and the blood urea nitrogen was 198 mg./100 ml.

Treatment was carried out as in Case 1, and within 48 hours her electrolyte values had returned to normal. Convulsions occurred repeatedly throughout that period despite anticonvulsant therapy and the maintenance of normal blood sugar and calcium levels. She died suddenly at 51 hours, however, and necropsy permission was refused.

COMMENT

In both cases hypernatraemia was caused by excessive administration of solute in relation to fluid intake owing to improper reconstitution of dried-milk formulae. In Case 1 the mother had prepared feeds, using double the powder content recommended, but she believed that one tablespoon contained one fluid ounce of water. In Case 2 the initial feeding history obtained seemed quite normal. It only became clear on specific questioning that the mother used the dried-milk scoop for measuring fluid in the belief that each scoop contained a fluid ounce of water. The feeding instructions issued by the manufacturers of three commonly used dried-milk preparations—namely, Ostermilk No. 2, full-cream Cow and Gate, and full-cream National Dried Milk—would be quite clear to most mothers (see Table), but none of those instructions make it absolutely clear that the measure supplied is for dried milk and not fluid. The National Dried Milk instructions do indicate that one fluid ounce is approximately two tablespoons and for that reason are the most explicit. It is probably quite fortuitous that in both cases Ostermilk No. 2 was the dried milk powder used, but further errors could probably be avoided if feeding instructions were even more simple than at present. Thus it should be made clear that the measure supplied is for dried milk only and not fluid, and that one fluid ounce is approximately equal to two tablespoonfuls.

Comparison of Feeding-tables for Normal Babies of Normal Weight at 1 Month (Extract from Manufacturers' Instructions)

Preparation	Dried-milk Content	Fluid Content
Ostermilk No. 2	Level measures, 3½	Hot water, fluid oz. 4
Cow and Gate (Full-cream)	„ „ 3½	Make up with hot (boiled) water to 4 oz.
National dried milk (Full-cream)	Amount of milk powder for each feed (in level measures), 2½ or 3	Boiled water in ounces (1 oz. = 2 tablespoons approx.), 3½ or 4

We wish to thank Professor J. O. Forfar for his advice and criticism, and Drs. J. W. Farquhar and W. M. McCrae for permission to publish details of the above cases.

Anaemia Due to Blood Loss from the Telangiectases of Scleroderma

Brit. med. J., 1967, **3**, 537–538

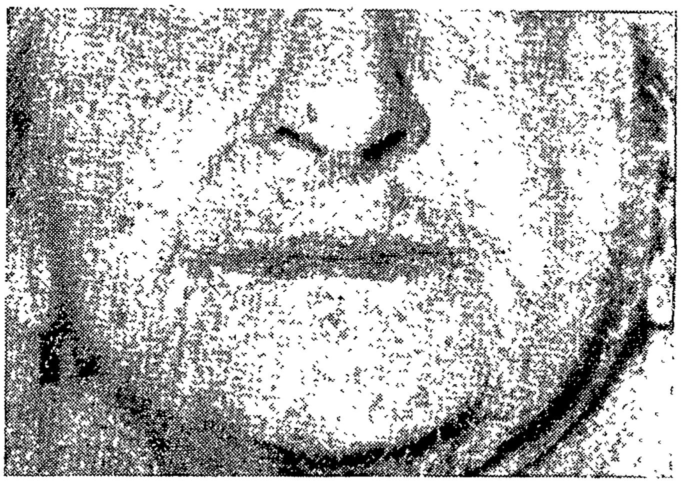
Telangiectases affecting the face, neck, oral mucous membranes, and extremities are not uncommon in scleroderma. In appearance they resemble closely those found in Osler–Weber–Rendu disease, though they are not hereditary (Verel, 1956; Winterbauer, 1964). However, it has been said that in contrast with Osler–Weber–Rendu disease the telangiectases of scleroderma rarely bleed and do not cause significant loss of blood (Winterbauer, 1964; Carr *et al.*, 1965). This report concerns two elderly women with scleroderma and telangiectases who have been gravely debilitated by severe hypochromic anaemia, for which the most likely explanation was gastrointestinal blood loss from telangiectases.

CASE 1

A 74-year-old widow was first seen elsewhere in 1958, when she complained of the symptoms of Raynaud's phenomenon for many years and the development of red blotches on the face. A diagnosis of scleroderma with telangiectases was made and as there was no evidence of systemic involvement a good prognosis was given. The blood was not examined, though two years previously her haemoglobin had been only 75%. Occasionally her nose had bled, but this had never been serious. None of her family had been troubled by anaemia or telangiectasia.

In October 1965 she was admitted to hospital because of increasingly severe symptoms of anaemia. She was pale, with striking telangiectasia affecting the face, lips, buccal mucosa, tongue, hands, and feet (see Fig.). The telangiectases varied in size up to a maximum of 5 mm. in diameter; they did not blanch on pressure. The skin of the fingers and toes was thickened and tense, with shortening of the terminal phalanges of some fingers. Elsewhere the skin was normal, but both normal and sclerotic skin was affected by telangiectasia. There were the signs of congestive heart failure. Blood pressure was 180/80 mm. Hg. Sigmoidoscopic examination was normal and mucosal telangiectases were not seen.

Investigations.—Hb 4.8 g./100 ml.; M.C.H.C. 24%; reticulocytes 5%; blood film—marked hypochromia; W.B.C. 13,200/cu. mm.; E.S.R. 14 mm./hour. Blood urea 65–59 mg./100 ml., plasma calcium 4.8 mEq/l., plasma proteins 6.6 g./100 ml., serum electrophoretic pattern normal. Antinuclear factor, gastric parietal cell, and thyroid antibodies negative. Urine normal. Faecal fat excretion 7.2 g./24 hours. E.C.G. normal. Radiological examinations: chest—marked cardiac enlargement, small pleural effusion on left side; hands—pronounced soft-tissue calcification affecting several digits; barium meal—dilated atonic oesophagus with impaired emptying, otherwise normal; barium enema—number of large saccules in sigmoid colon.



Case 1. Telangiectases affecting face and lips.

The principal cause of the congestive cardiac failure was judged to be the severe anaemia. She was treated with diuretics and carefully transfused. Two weeks later the haemoglobin was 13.8 g./100 ml.; she was feeling better and was no longer in heart failure. However, despite iron by mouth her haemoglobin fell during the next six weeks to 10.5 g./100 ml., but after a further six months her haemoglobin was 12.4 g./100 ml. (M.C.H.C. 32%, reticulocytes 3.2%), though she had had further bleeding from the nose necessitating cautery of small telangiectases in both nares.

CASE 2

A 73-year-old widow, first seen in May 1957, complained of pain and tenderness in the tips of the fingers of both hands which had developed suddenly one year previously. The skin was thin and atrophic and the hands were blue and cold. Radiological examination showed small erosions of the tips of the terminal phalanges. The haemoglobin was 13.3 g./100 ml. and the peripheral blood film normal.

A diagnosis of scleroderma was made. She was seen at frequent intervals with recurrent ulceration of the fingers and Raynaud's phenomenon. One year later telangiectases on the face, lips, and hands were noticed. None of her relatives had had similar lesions. A radiograph of the hands in 1960 showed calcification of the tip of one index finger. Barium study of the oesophagus with the patient in the prone position showed no peristalsis.

In January 1965 she was admitted to hospital because of shortness of breath on effort for six weeks and melaena for four days. She was pale and now had more numerous telangiectases on the face, lips, and arms; the buccal mucosa was spared. The hands showed marked sclerodactyly, the skin being thickened and atrophic with scarring of the fingers and wasting of the pulp. The skin elsewhere, notably on the face, was of normal texture. There were signs of mild congestive cardiac failure. Blood pressure was 120/60 mm. Hg. Sigmoidoscopic examination was normal.

Investigations.—Hb 7.5 g./100 ml.; reticulocytes 11.2%; blood film—hypochromia; M.C.H.C. 31%; W.B.C. 9,600/cu. mm.; E.S.R. 34 mm./hour; serum iron 6.8 μg./100 ml. Blood urea 39 mg./100 ml.; plasma calcium 5 mEq/l.; plasma phosphate 3.7 mg./100 ml. Plasma proteins 5.5 g./100 ml.; serum electrophoretic pattern normal. No L.E. cells detected; antinuclear factor, gastric parietal cell, and thyroid antibodies negative. Faecal fat excretion 2.2 g./24 hours. E.C.G. normal. Urine normal. Radiological examinations: chest—normal; hands—no soft tissue calcification; barium meal—normal stomach and small intestine; barium enema—numerous small diverticula throughout colon.

After blood transfusion and administration of iron the haemoglobin rose to 12.6 g./100 ml. Digitalis and diuretics were given in addition, and the signs of cardiac failure disappeared. Over the course of the next 14 months, despite oral and parenteral iron, the patient required blood transfusion on four occasions. Occult blood was detected in the stools repeatedly. Later the gastrointestinal blood loss during a 15-week period of study using ^{59}Fe and a whole-body counter (Callender *et al.*, 1966; Holt *et al.*, 1967) was estimated to be 1.5 litres per 100 days. Absorption of an orally administered dose of 5 μc. ^{59}FeCl was 90%, normal for a patient with iron deficiency. Frank bleeding from telangiectases on the inner aspect of the lips has since occurred.

DISCUSSION

Telangiectases occur most frequently in the variety of scleroderma that consists of sclerodactyly, Raynaud's phenomenon, and subcutaneous calcinosis in the absence of marked systemic involvement. It characteristically has a good prognosis (Tuffanelli and Winkelmann, 1961; Winterbauer, 1964; Carr *et al.*, 1965). Both the above patients had this variety of scleroderma, which would have caused them little trouble had they not been disabled by anaemia.

The most likely explanation for their anaemia was continuous bleeding from telangiectases in the gastrointestinal tract. The blood loss is just compensated for by oral iron in Case 1, but the second patient required periodic blood transfusion. Both patients had diverticulosis of the colon, but the nature of the blood loss made it unlikely that this was the underlying cause. It is of interest that in Case 1 the radiological features of the diverticula were those of scleroderma (Heinz *et al.*, 1963). Scleroderma may be associated with intestinal malabsorption (Sonneveldt *et al.*, 1962), and the faecal fat excretion in Case 1 was marginally raised. However, poor absorption of iron was unlikely to be a factor in the pathogenesis of anaemia in either patient, since iron given therapeutically in the first case was sufficiently absorbed to correct the anaemia, and in the second case absorption of ^{59}Fe was normal.

The telangiectases of scleroderma cannot be distinguished clinically from those occurring in the Osler–Weber–Rendu disease (Verel, 1956; Winterbauer, 1964). It is therefore surprising that stress has been laid on the apparent absence of a haemorrhagic tendency (Winterbauer, 1964; Carr *et al.*, 1965). There is no doubt that internal telangiectases occur in scleroderma as in Osler–Weber–Rendu disease, since two patients discussed by Winterbauer who suffered gastrointestinal haemorrhage were shown to have mucosal telangiectases in the stomach, and in one case in the large bowel also.

We believe it probable that the telangiectases of scleroderma can cause clinically significant blood loss. They occur mainly in a variety of scleroderma that is otherwise benign, and, as this usually affects elderly patients, iron-deficiency anaemia should be searched for frequently, since any symptoms of anaemia may be wrongly attributed to age and ignored.

Dr. H. R. Vickers kindly referred the second patient to us.

Current Practice

Transport of Invalids by Air

K. G. BERGIN,* O.S.J., M.A., M.D., D.P.H., F.R.AE.S.

General practitioners not infrequently are uncertain whether a patient is fit to travel by air. This article is based on a guide prepared to advise in general terms on the principal factors to be considered. The first guide was prepared some years ago, but it has since been revised on several occasions, the last time being by the Medical Committee of the Aerospace Medical Association.

Introduction

The number of persons travelling by air increases every year, and included in that total is an appreciable number of invalids suffering from illnesses of varying degrees of severity from the slightly indisposed to those near the end of a terminally fatal disease.

Sick persons, including those at both extremes of the age scale, tolerate modern flying conditions with very little, if any, discomfort. The number of invalids wishing to travel by air who have to be refused passage is steadily decreasing, and the great majority of cases benefit by the advantages air travel has to offer over surface travel, including speed, smoothness, and comfort. In many cases this form of transport is not merely desirable but actually life-saving.

Aircraft

Cabins.—All modern aircraft have pressurized cabins, the advent of which has greatly simplified problems of oxygen supply, though it has brought a number of other problems in its train. Briefly, the principle of pressurized cabins is to introduce air by means of a mechanically driven impeller, so that a controlled pressure is maintained in the cabin of the aircraft irrespective of the ambient atmospheric pressure. Aircraft design requirements make it necessary for the pressure in an aircraft to be slightly lower than the normal sea-level atmospheric pressure (14.7 lb. per sq. in.), and it is this factor which is chiefly responsible for the few specific contraindications to air travel. The slightly lowered air pressure means that the air density in the cabin is somewhat reduced, and that therefore a little less oxygen is present in the inspired air than is the case at sea level. In most modern aircraft the cabin air pressure is maintained at an equivalent of 6,000 ft. to 8,000 ft. (Table I).

TABLE I.—*Effects of Cabin Pressurization*

Aircraft	Concorde	Boeing 747	VC-10	Boeing 707	DC-8	Trident	Comet 4	BAC 111	Caravelle
Maximum differential pressure lb./sq. in.	10·7	8·9	9·0	8·6	8·77	8·25	8·75	7·5	8·25

15,000 ..									

S.L. = Sea level.
It is normal practice to operate at cabin altitudes 300–500 ft. higher than those stated above in order to give smoother cabin altitude control.

Fig. 1 shows the fall in the oxygen tension in the lung alveoli as cabin altitude increases. Fortunately, the high affinity of haemoglobin for oxygen means that arterial oxygen saturation does not fall proportionately rapidly. As Fig. 2 indicates, a cabin altitude of 5,000 ft. leads to a fall in arterial oxygen saturation of only 3% below the ground-level normal of 96%. This slight degree of hypoxia may affect patients with significantly impaired cardiovascular or respiratory reserves, and such individuals should accordingly not travel by air without prior consultation with the medical department of the airline concerned, when special arrangements can be made to supply supplementary oxygen for individual cases.

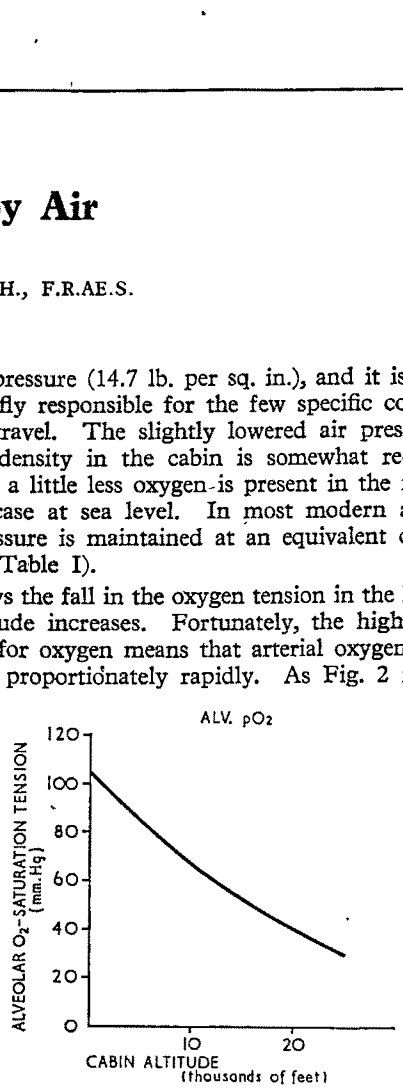

FIG. 1

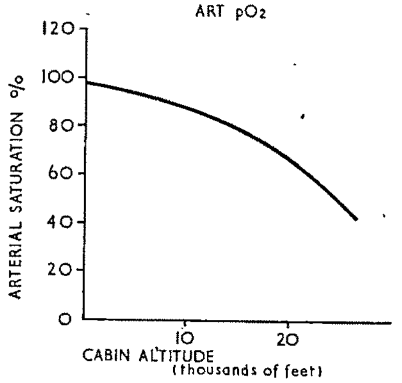

FIG. 2

Operational Characteristics.—It is sometimes helpful to know the operational characteristics of the aircraft in which the patient will fly—although nowadays conditions in the cabin are so regulated both as to actual conditions and rate of change

TABLE II.—*Typical Aircraft Comparative Data*

Aircraft	Boeing 707–436	Vickers Super VC10	Caravelle VIN	BAC 1-11 300	Trident I	Douglas DC-9-30	Concorde
Take off distance sea level (ft.)	11,000	9,050	6,200	7,150	7,900	7,300	9,650
Max. take off weight (lb.)	311,750	335,000	105,820	87,000	115,000	108,000	350,000
Take off speed at max. take off weight (m.p.h.)	183	181	153	146	164	—	230
Typical initial rate of climb (ft./min.) ..	2,500	2,500	2,500	2,500	2,900	3,000	3,300
Typical cruise speed (m.p.h.)	545	545	510	540	580	560	1,320
Normal operating altitude (ft.)	30/40,000	30/40,000	25/30,000	25/30,000	25/31,000	25/35,000	50/65,000
Typical average rate of descent (ft./min.) ..	1,500	2,000	2,400	2,000	2,100	2,000	2,400
Range, average statute miles	3,650	3,550	1,325	820	870	780	3,800
Average capacity (lb.)	44,600	43,500	17,100	21,600	19,000	24,300	25,000
Landing distance at max. landing weight (ft.)	7,800	6,250	5,300	5,560	6,260	4,850	8,450
Landing speed at max. landing weight (m.p.h.)	168	159	145	143	160	146	175
Max. passenger capacity	162	157	90	79	100	107	120
Cabin differential (lb./sq./in.)	8·6	9·0	8·1	7·5	8·25	7·46	10·7

that no doctor need fear for his patient's safety. As a matter of interest operational data of some current aircraft in common use are given in Table II.

An essential component of all large passenger aircraft is emergency oxygen equipment which comes into use automatically in the event of an emergency, when the cabin pressure falls for one reason or another. In addition, when a patient requires oxygen an invalid oxygen set can be put on board for his exclusive use. Fittings for stretcher cases are to be found on most large passenger aircraft.

All aircraft have seat belts, and seat backs and fittings are constructed so that in the event of an emergency landing or severe braking injury to passengers is minimized.

Finally, all airlines carry first aid kits for use should they be required.

Cabin Staff.—A proportion of air stewardesses are State registered nurses and all cabin staff have training in elementary first aid and care of the sick.

Consequences of Atmospheric Change

Apart from specific disabilities it is important to know of certain conditions which can be brought about by the changing physical environment of flight on ascent and descent. They may be of no concern to the passenger, or cause merely passing discomfort; in some cases they may produce disabling pain. The group heading under which the commoner conditions are included is known as dysbarism. The commoner manifestations met with in flying are described below.

Otitic Barotrauma or Barotitis Media.—This is cause by failure to equalize pressure in the middle and outer ear as atmospheric pressure rises when the aircraft descends, leading to tension and varying degrees of trauma to the tympanic membrane. It can vary from dull transient earache to severe disabling pain. It is brought about by lack of patency of the eustachian tube usually due to nasopharyngeal infection.

Sinus Barotrauma or Barosinusitis.—This condition is brought about by similar conditions, namely inadequate ventilation of a sinus resulting in a pressure gradient—the pain is caused by air trapped in the sinus expanding. It is very sharp and sudden in onset and has been likened to a blow on the head with a hard instrument.

Aeroembolism.—This is very rarely met with in pressurized cabins. Pain in the joints is caused by release of nitrogen into the tissues. It is relieved by the administration of oxygen.

Aerodontalgia—is toothache brought on by expansion of gas in a badly filled cavity. It is rare.

Expansion of gases—whether in the gut or the thorax can lead to discomfort and in some cases severe pain. It is usually of no clinical significance, but in the thorax it can lead to serious conditions such as mediastinal shift (Figs. 3 and 4).

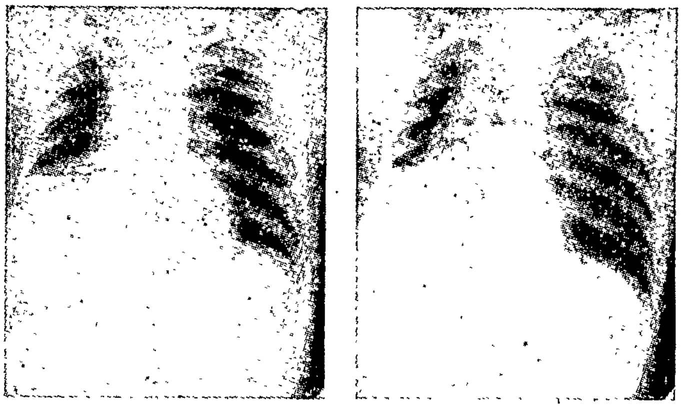
Hypoxia.—As stated earlier, pressurized cabins maintain an atmospheric pressure approximately equivalent to 8,000 feet at whatever altitude the aircraft may be flying. There is therefore a small degree of hypoxia. Any patients with a decrease of the pulmonary ventilating area or coronary deficiency may experience exaggerated symptoms for which personal emergency oxygen should be provided.

Motion Sickness.—This is very rare in modern jet flying, which is usually above bad weather—but there are three occasions when it may occur, namely clear air turbulence, when descending through bad weather to airports, or when delayed in the airport circuit while other aircraft are landing. Such transient sickness can be effectively dealt with by well-known remedies with a hyoscine content, in addition to such measures as loosening constrictive collars, lying in the recumbent position, and avoidance of overheating. Severe attacks must be carefully watched in the case of diabetics or recent peptic perforation, but such episodes are very rare.

Assessment of the Patient

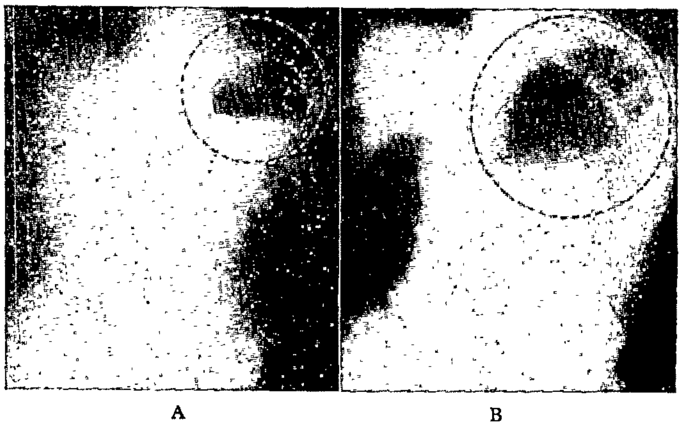
General basic principles should be considered before a patient flies.

(a) Is he fit to travel by any means of transport? If the answer is "no," further consideration of air travel can be ruled out.



A B

FIG. 3.—Radiographs showing pneumothorax at 1,000 ft. (A) and 10,000 ft. (B) respectively.



A B

FIG. 4.—Radiographs showing expansion of intestinal gases under lowered conditions of atmospheric pressure. A, Ground level; B, 40,000 ft.

(b) Is he fit to travel with other members of the public? There are certain cases which for reasons of public policy cannot be carried in a public transport vehicle. In public transport aircraft aesthetic considerations and the comfort of the other passengers demand that a patient should look and smell normal and behave normally. If these requirements cannot be met a private charter aircraft should be considered. The first type of case of this sort which cannot be carried is that which either in appearance or odour is objectionable to fellow passengers. Such cases include open wounds or lesions of exposed parts, such as the face, a colostomy over which the patient has little or no control, grossly disfiguring conditions, or incontinence of urine or faeces. It should be remembered that a colostomy over which an individual has control at ground atmospheric pressure may well become uncontrollable in conditions of lowered pressure. Patients with carcinoma at times have an extremely unpleasant smell and in the confined space of an aircraft cabin can be most objectionable. Secondly, cases should be refused which by reasons of their behaviour are objectionable to other occupants of the aircraft. Such cases would include those prone to extreme noisiness, peculiarities of habit, incontinence, or major epilepsy, and cases of mental illness when not accompanied by an attendant or suitably sedated.

(c) The stability of the patient's condition should be considered. It should be ensured as far as possible that there is not likely to be a medical crisis en route necessitating diversion of the aircraft from its prescribed course. Apart from the great inconvenience and cost caused it can in certain cases, as for example long trans-oceanic flights, imperil the safety of the aircraft. It should be possible to ensure against the likelihood of this with a fair degree of certainty.

Contraindications for Acceptability

Cardiovascular

Cases of uncompensated heart disease and severe angina pectoris should not travel by air unless special arrangements are made and extra supplies of oxygen are available. Unhealed coronary thrombosis is a contraindication to air travel. At least two to three months should have elapsed since the acute episode, and if there are residual symptoms the medical department of the airline should be consulted.

Cases of controlled hypertension will normally be accepted without restriction, but the value of a sedative before flight should be remembered. Where there is evidence of cardiac, ocular, or renal complications, the airline medical department should be advised.

Persons who exhibit cyanosis, severe disturbance of rhythm, persistent arrythmias resulting in recurrent prostration, syncope, or shocklike conditions, those with markedly enlarged hearts, extreme valvular stenosis, convalescent myocardial infarction, marked exertional angina, severe hypertension and hypertensive encephalopathy, or any other condition which restricts the cardiac reserve to such an extent as to render the patient unable to climb one flight of stairs without production of symptoms or severe dyspnoea should be carefully evaluated before they are advised that air travel is safe for them.

A patient with a history of thrombotic or venous disease should be instructed against remaining immobile for long periods during air flight. Immobility and the associated venous stasis in the limbs are believed to be important factors in the development of "passenger phlebitis," which may result in pulmonary infarction.

Blood Dyscrasias

Flying is contraindicated in blood dyscrasias where the red cell count is less than 2.5 million/mm., or the haemoglobin less than 50%. If a blood transfusion is given, the aim should be to raise the haemoglobin to over 60% before flight. All cases of blood dyscrasia other than simple mild anaemias should be referred to the airline medical department because of their known liability to symptoms from minor degrees of oxygen lack. Acute leukaemias which have recently been treated with *x* rays constitute a contraindication to air travel on account of the possibility of haemorrhage under conditions of lowered oxygen tension.

Respiratory

Acute upper respiratory tract infections.—The common cold, sinusitis, and pharyngitis may cause blockage of eustachian tubes and sinus foramina. Inability to ventilate the middle ears and sinuses to compensate for pressure changes during climb and descent may cause severe pain, and patients with these disorders should postpone their flight until the condition has subsided. It should be remembered that chronic naso-pharyngeal conditions in which the patency of the eustachian tubes is impaired can give more trouble than the acute phase when congestion is not so marked.

Asthma and bronchitis.—Sufferers from asthma, chronic bronchitis, and emphysema should be assessed for the degree of respiratory embarrassment present, and the value of a sedative should be remembered. The uncontrolled coughing and copious offensive sputum which may be produced in cases of severe bronchiectasis may make patients with the condition unacceptable in spite of reasonable respiratory efficiency.

Tuberculosis, Pneumothorax, etc.—Respiratory disorders affecting exercise tolerance should be considered in a similar manner to cardiovascular diseases, and where there is any doubt the attending physician should make special arrangements with the airline medical department. Cases of active pulmonary tuberculosis must be considered to be potentially infective under conditions of reduced air pressure and cannot therefore be accepted. Quiescent or healed cases may travel without restriction. If an artificial pneumothorax is present, seven days must have elapsed since the last refill and the lung must be at least three-quarters expanded, because of the effects of reduced pressure on trapped gas.

Apart from the question of reduction in the available area of lung tissue, another important factor is the possibility of mediastinal or diaphragmatic shift (Fig. 3) as a result of operation or disease. Such a condition would be aggravated under changed conditions of pressure, and where such a liability exists flying should be avoided.

Persons whose vital capacity is 50% or less do not do well in unpressurized aircraft unless a flight altitude of less than 5,000 feet is maintained. Pulmonary function and reserve should be evaluated in order to determine whether persons with pulmonary emphysema or severely limited ventilation, arising from pulmonary fibrosis, should travel by air.

Gastrointestinal

The reduced cabin air-pressure allows intestinal gas to expand. Resulting distension means that flying is contraindicated in patients who have recently undergone abdominal operations—10 days post-operation being the minimum acceptable time after uncomplicated appendicectomy, etc. The risk of perforation and haemorrhage from this cause in patients with active peptic ulceration means that the airline medical department must be consulted in these cases prior to flight. Trained colostomy patients may fly provided that they are well acquainted with measures for the control of their colostomy, which is likely to be more active in the air. In all such cases any increased tendency to vomit must be watched and control measures taken.

Infection

Cases of infectious diseases, including poliomyelitis and trachoma, cannot of course travel in public transport aircraft. Special arrangements can usually be made for the carriage of poliomyelitis cases after the acute and infectious stages have passed.

Neuropsychiatric

The safety of the other passengers and crew should be evaluated when a person with a psychiatric disorder is being considered for travel by air. Persons manifesting unpredictable behaviour or those who require heavy sedation or restraint should not fly on commercial transports. However, the judicious use of medication should reduce the incidence of neuropsychiatric problems.

Age

Old people with well-compensated cardiovascular and respiratory systems tolerate air flight excellently. There are no contraindications to flying based on advanced age alone. Equally, the newly born tolerate air travel well and there are no lower limits to such cases.

Central Nervous System Disorders

Most of these cases are covered by the "look and smell normal, and behave normally" rule. Uncontrolled epilepsy and faecal or urinary incontinence would therefore be absolute contraindications to travel in public transport aircraft. It must be remembered that epilepsy is aggravated by mild hypoxia and hyperventilation. Cases of Parkinson's disease, for example, could be carried by special arrangement, and cases of mental disorder might be accepted under sedation, or if accompanied by an attendant.

Patients who have had poliomyelitis are acceptable for air travel provided one month has elapsed since the onset of the disease, the disease generally being considered to be non-infectious after such a period. If the patient is not ambulatory a special attendant is required. Occasionally special arrangements can be made with some airlines to transport persons recovered from the bulbar type of poliomyelitis. In this type of case preparation must be made by the airline concerned to have the proper power supply (correct voltage and wattage) for activation of the portable respirator, if this apparatus is required.

Metabolic Disorders

Diabetes is not a contraindication to air travel provided the patient is well stabilized, severe cardiovascular disease is absent, and the individual is instructed concerning the importance of feeding at physiological intervals rather than being guided by local times, which can change by several hours in flying. Oxygen should be available in these cases, because they are particularly sensitive to hypoxia. Appropriate preventive measures should be taken if the patient is liable to motion-sickness.

Airsickness is, however, rare nowadays in aircraft which fly at high altitudes, because less turbulence is encountered. It has been found by experience that remedies containing hyoscine in a dosage of 1/100 gr. (0.6 mg.) constitute the best routine prophylactic for adults.

Pregnancy

The majority of international airlines carry pregnant women up to and including the 32nd week of pregnancy, and this may be extended on domestic services. The restriction is introduced in order to avoid, as far as possible, the risk of birth while airborne. If a passenger is known to be prone to abortion flying may be contraindicated up to the third month of pregnancy. In this connexion it should be remembered that though weather conditions may be good at the beginning of a flight they may deteriorate en route and extreme turbulence may occasionally be encountered. This might result in premature and precipitate labour.

Terminal Stage of Life

There is no contraindication to patients near to death flying, but patients *in extremis* should not be accepted for air travel because of the difficulties associated with deaths en route.

TABLE III.—*Summary of Restrictions on the Carriage of Invalids*

Condition	Limiting Factors	Restrictions and Precautions
Anaemias Blood dyscrasias Reticuloses	Red cell count below 2½ million per cu.mm. Haemoglobin below 50% Severe involvement of mediastinal lymph glands Severe constitutional upset Radiation sickness Tendency to haemorrhage	Airline medical department must be consulted Haemoglobin should preferably be raised to 60%, by transfusion if necessary Oxygen must be available
CARDIOVASCULAR DISEASES		
A. Angina pectoris Compensated heart disease	Reasonable threshold for exercise without symptoms	Airline medical department should be notified Oxygen must be available
B. Uncompensated heart disease	Evidence of failure	Each case must be considered on its merits
C. Coronary occlusion	Minimum of 8–12 weeks post-occlusion. If residual symptoms are present, case must be treated as A or B above	As A or B above
D. Hypertension:		
(i) Controlled and asymptomatic		Sedative may be indicated. Airline should be notified
(ii) Complicated	Impairment of cardiac, renal or C.N.S. function	Airline medical department must be consulted Oxygen must be available
RESPIRATORY DISEASES		
A. Acute upper respiratory tract infections	Eustachian or sinus catarrh	Air travel temporarily contraindicated
B. Asthma, bronchitis, emphysema, and non-infectious fibrotic diseases	Exercise tolerance only moderately impaired	Airline medical department should be notified Oxygen must be available If exercise tolerance is severely impaired, special arrangements must be made
C. Pulmonary T.B.		
(i) Active	Tubercle bacilli in sputum	Cannot be carried while regarded as infectious
(ii) Quiescent or healed	Degree of impairment of function	As B above. Seven days must have elapsed since refill of artificial pneumothorax or pneumoperitoneum. Lung must be ¾ expanded
D. Pneumonia	Must be resolved. Residual impairment of function	As B above
E. Bronchiectasis	(i) Impairment of function	As B above
	(ii) Copious offensive sputum	Cannot be carried, except by special arrangement
GASTROINTESTINAL DISEASES		
A. Peptic and bowel ulceration		
(i) Active	May bleed or perforate under reduced pressure, or be aggravated by motion sickness Should not travel within 3–4 weeks of haematemesis or melaena	Air travel contraindicated except in emergency Airline medical department must be consulted
(ii) Healed		
B. Post-operation	Distension of bowel under reduced pressure	Airline medical department must be notified Minimum of 10 days should have elapsed since operation Hyoscine to prevent airsickness if necessary
C. Colostomy	Overactivity and poor control	Airline medical department must be consulted
RENAL DISEASES		
A. Calculus	Frequent attacks of colic	Normally no restriction Hyoscine to prevent airsickness
B. Other	Degree of impairment of function	Airline medical department should be consulted

(Continued on next page)

TABLE III.—*Continued*

Condition	Limiting Factors	Restrictions and Precautions
C.N.S. DISEASES		
A. Epilepsy	Frequent seizures	Special arrangements must be made if fits are uncontrolled
B. Mental disease	Behaviour must be normal under mild stress	Special arrangements, including sedation and an attendant normally required
C. Faecal or urinary incontinence		Cases will not normally be be carried
INFECTIOUS DISEASES	Infectious phase	Will not be carried
METABOLIC DISEASES		
A. Diabetes		
(i) Stable and uncomplicated	Patient must understand his own case, and be able to administer his own insulin etc.	Time changes must be taken into account Airline medical department should be notified and hyoscine given if necessary
(ii) Unstable or complicated		Special arrangements must be made
B. Liver diseases	Ascites or severe impairment of function Possible rupture of abscesses	Airline medical department must be consulted
ELDERLY	Respiratory and cardiovascular function must be adequate. Bowel and bladder control must be normal	None, unless patient is not fully ambulant, when special arrangements should be made
PREGNANCY		
(i) First trimester		History of abortion is relative contraindication Hyoscine to be given if necessary
(ii) 12–32 weeks		None if normal. Airline medical department to be notified Oxygen to be available
(iii) Beyond end of 32nd week		Will not normally be carried on international flights

Queries

In the majority of the larger airlines there are specialist medical officers who have a great deal of experience in problems of the carriage of invalids by air, and there is a department which deals with the care and transport of such passengers to which all such inquiries should be addressed. Application should be made to the airline concerned, when usually a questionary will be sent to be completed by the patient's private doctor. This will then be considered by the medical department, and a decision will be made on whether the patient is acceptable for air travel. If the answer is in the affirmative a briefing form is completed alerting the airline officials en route of the special services which will be required and setting in train the provision of such requirements from the port of departure through to the final destination. These arrangements may include the attendance of doctors, or the administration of drugs en route, the provision of certain items of medical equipment and oxygen sets, nursing facilities, or ambulance requirements.

Conclusion

Experience has shown that increasing numbers of seriously ill patients can be carried by air, and many of course benefit from the availability of this form of transport. The advantages offered by rapid transit, smooth flight at high altitudes, controlled atmospheric conditions within the cabin, coupled with the medical facilities available in flight such as emergency oxygen supplies, make air travel a most useful form of transportation for the seriously ill person who wishes to travel with a minimum of physical upset or discomfort.

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

"Arc Eye"

A.—*What is the best topical application for "arc eye"?*

A.—Local anaesthetic drops may be necessary for examining an eye after exposure to ultraviolet radiation, but their continued use is inadvisable. Adrenaline eye-drops are helpful in mild cases and cold compresses produce some alleviation of symptoms. Light should be excluded by bandaging the eyes.

Oral Contraceptives and Mitral Stenosis

Q.—*Is there any evidence that oral contraceptives might increase fibrin deposit on the mitral valves in cases of mitral stenosis?*

A.—It is very unlikely that thrombosis as such plays any part at all in the fibrotic narrowing of the mitral valve which leads finally to mitral stenosis. Therefore oral contraceptives should not have any effect whatsoever on the rheumatic mitral valve.

Treatment of Barbiturate Poisoning

Q.—*What are the main points in the treatment of barbiturate poisoning, and what are the indications for the administration of bemegride?*

A.—Bemegride, though introduced as an antidote for acute barbiturate poisoning,[1] is an analeptic with no specific action against barbiturates. It and other analeptics have no place in the treatment of barbiturate poisoning.[2]

Since there is no antidote, the treatment consists in the maintenance of vital functions. Respiration has to be safeguarded by keeping the airway clear, and, if necessary, by applying oxygen and artificial respiration. Shock will require vigorous management, the blood pressure being maintained with metaraminol. Hypothermia, hydration, and acid–base balance may all require active attention. Intensive nursing care is most important. These measures alone will be successful in 95% of cases. Gastric aspiration and lavage should be undertaken only within four hours of the ingestion of the tablets and if the lungs are protected by an adequate cough reflex or a cuffed endotracheal tube.[3]

Forced diuresis and peritoneal- and haemodialysis should be used only in exceptional circumstances—for example, when the condition deteriorates despite intensive measures to support vital functions. Treatment will not be complete unless the psychiatric aspects of the case are investigated and dealt with.

Clinicopathological Conference

A Case of Hypertension, Anuria, and Uraemia

DEMONSTRATED AT THE ROYAL POSTGRADUATE MEDICAL SCHOOL

Clinical History

DR. O. WRONG: The patient (Case No. 300365, P.M. No. 11312) was a married woman aged 39 at the time of her death from uraemia. There was no known history of hypertension or renal disease. In 1950 and 1952 she had had pregnancies which were apparently uneventful. In 1953 and 1955 further pregnancies were complicated by hypertension—noted at 37 and 12 weeks, respectively—but she went to term successfully. In 1957 her fifth pregnancy was also complicated by hypertension, and she prematurely delivered a living child at 36 weeks.

After the fifth pregnancy she was found to have persistent hypertension, which was investigated in New Zealand. Her fundi were said to show grade III retinopathy, while an intravenous pyelogram showed no abnormality. Her hypertension was thought to be essential in type, and treatment with hypotensive drugs was started. In 1963 she became pregnant again, and in March 1964 this sixth pregnancy was terminated at 29 weeks because of a blood pressure of 210/130, which persisted despite treatment with guanethidine and polythiazide. The blood-urea concentration was 48 mg./100 ml. and the haemoglobin level 10 g./100 ml. Subsequently she was well enough to resume domestic chores, look after her children, and play an occasional round of golf. She continued to take drugs for her hypertension. In February 1965 she had a short illness with back pain, fever, and slight urinary frequency. From that time on she had nocturia and frequent nausea and anorexia. In April she stopped taking her guanethidine because of this nausea.

Progress

By the end of April she was more nauseated and noticed that her urinary output was scanty. On 6 May she became breathless and was admitted to her local hospital with pulmonary oedema and a blood-urea level of 330 mg./100 ml. She was treated with digoxin, methyldopa, guanethidine, and ampicillin, being transferred to Hammersmith Hospital on the following day. Here she was found to be pale and confused, with a pyrexia of up to 39° C. There were multiple bruises on the skin. The jugular venous pressure was raised, but there was no ankle or sacral oedema. Her blood pressure was 170/105 mm. Hg, and the optic fundi showed scattered haemorrhages and exudates but no papilloedema. There was evidence of moderate cardiac enlargement and a left pleural effusion, and widespread rhonchi were heard. The kidneys could not be felt, and she was unable to pass urine.

The blood urea was 350 mg./100 ml., serum sodium 130, potassium 5.8, and bicarbonate 24 mEq/l. The serum albumin was 3.5 g. and the globulin 1.9 g./100 ml., with a normal electrophoretic pattern (one month later the albumin was 2.3 and the globulin 5.5 g./100 ml., with an increased gamma-globulin fraction). A radiograph of the chest showed appearances consistent with a left pleural effusion and consolidation or oedema of both lower lobes; the right kidney appeared rather small in the abdominal *x*-ray film, but neither kidney could be clearly seen; a radiograph of the hands was normal. The haemoglobin level was 6.3 g./100 ml. (M.C.H.C. 28%) and the stained film showed fragmented and crenated red cells. The platelet count was 171,000/cu. mm. The antistreptolysin-O titre was 50 units/ml. An electrocardiogram showed left ventricular hypertrophy and non-specific T-wave changes; at a later date she was found to have auricular fibrillation.

Her uraemia was controlled with peritoneal dialysis and her hypertension treated with methyldopa. Details of the clinical course are shown in Fig. 1. She remained almost totally anuric for the rest of her life, the few drops of urine she did pass containing many red cells and 5 grammes of protein per litre but only scanty granular casts. Despite aspiration of her left pleural effusion and various antibiotics she repeatedly showed evidence of pulmonary consolidation with fever and purulent sputum.

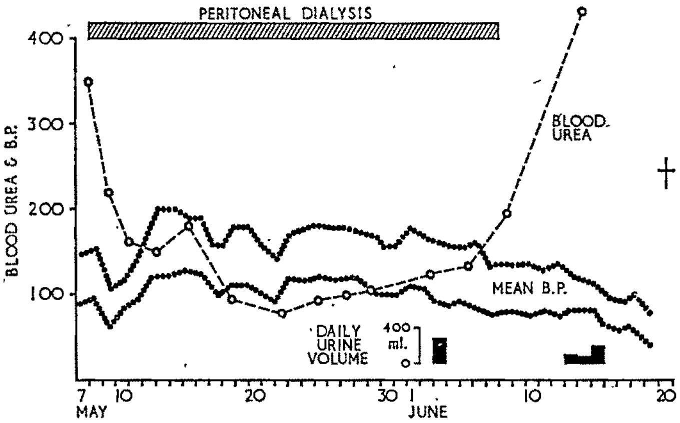

FIG. 1

On 15 May *Klebsiella* was grown from the peritoneal fluid, and she had slight abdominal pain and tenderness. Kanamycin was given, its dosage being controlled by blood levels. A renal biopsy on 25 May showed evidence of benign hypertension only, without either glomerulitis or the characteristic changes of malignant hypertension. Because of the failure to explain adequately her anuria a retrograde pyelogram was performed on 4 June, but showed no abnormality. Corticosteroid therapy was also started on that day (prednisone 60 mg./day) on the remote chance that she had a polyarteritis that was not revealed by the renal biopsy. Over the next few days peritoneal dialysis became increasingly difficult, with repeated growth of *Escherichia coli* in the fluid and occasional

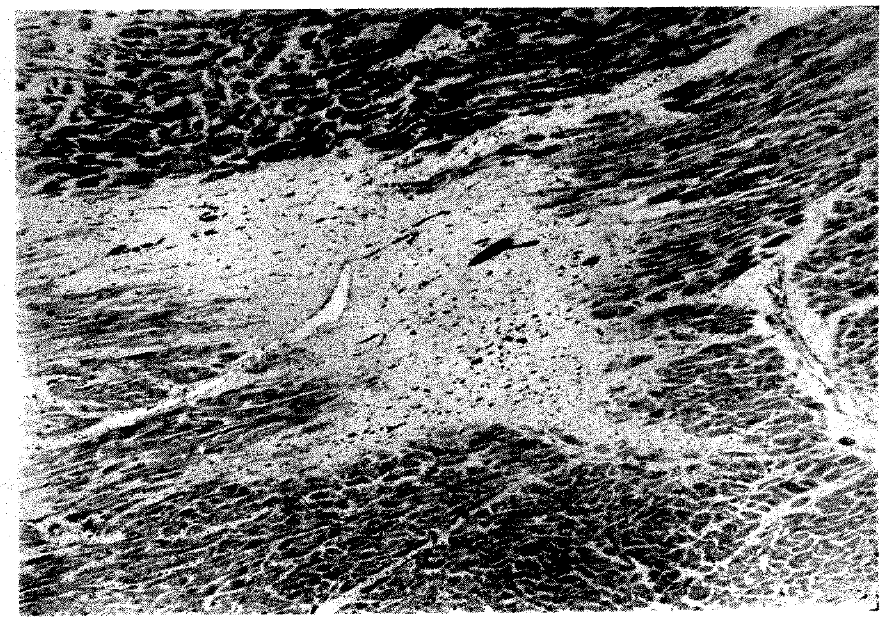

FIG. 2.—Myocardium of left ventricle showing a focus of recent necrosis. (H. and E. ×40.)

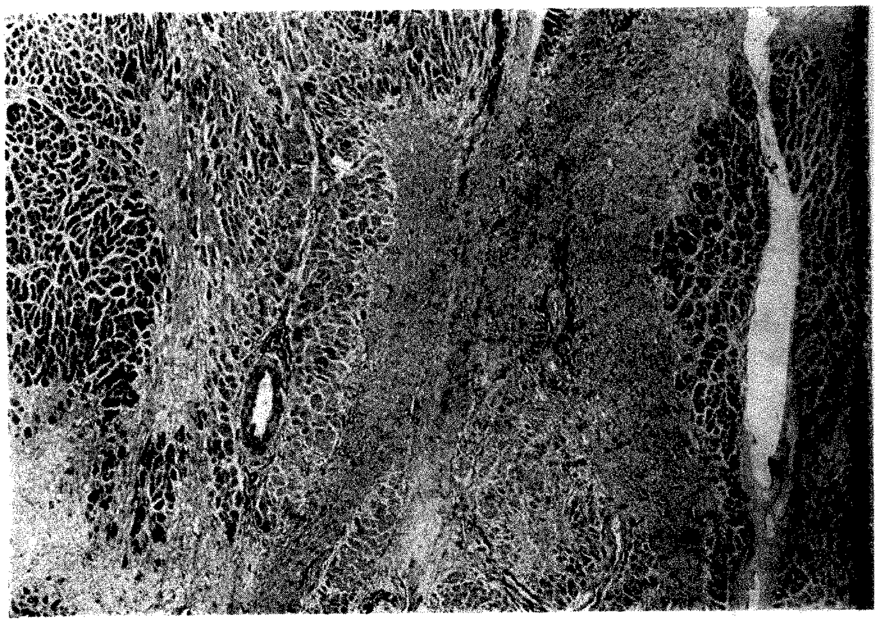

FIG. 3.—Myocardium of left ventricle showing organization of an older necrotic region. (Picro-Mallory. ×40.)

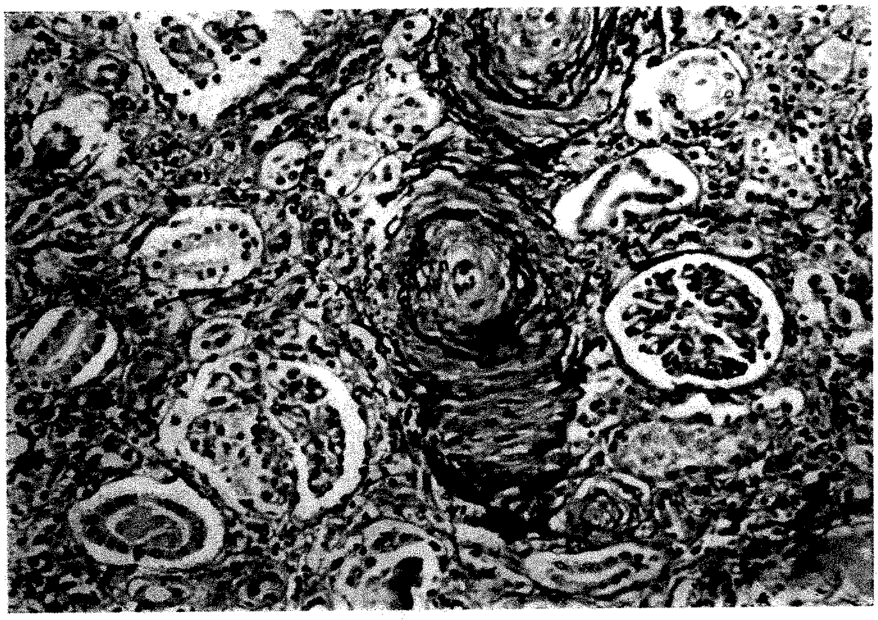

FIG. 4.—Renal cortex with relatively normal glomeruli, a few atrophic tubules, and an afferent arteriole with its lumen almost obliterated by intimal thickening. (Elastic-van Gieson. ×190.)

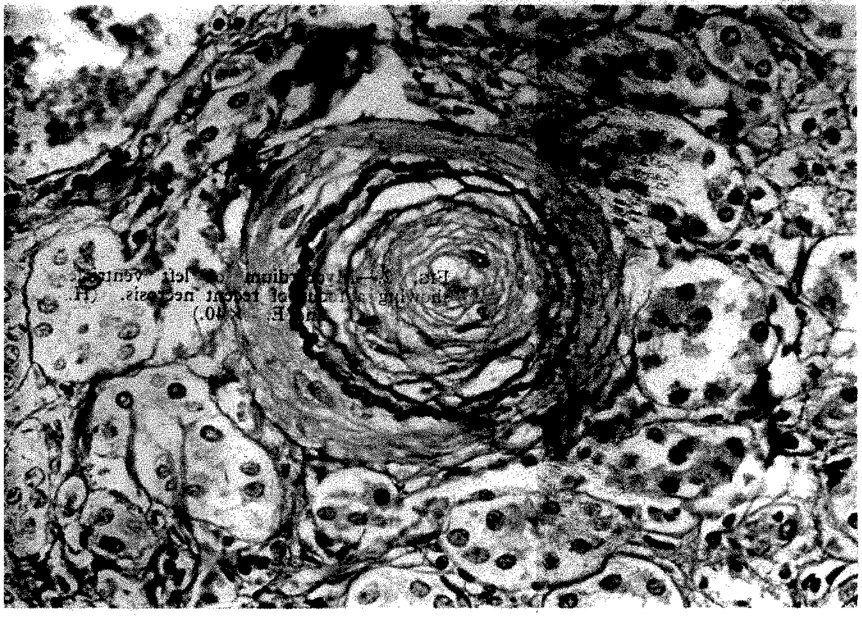

FIG. 5.—Afferent glomerular arteriole with its lumen almost completely occluded by the typical " onion skin " intimal proliferation of malignant hypertension. (Elastic–van Gieson. ×400.)

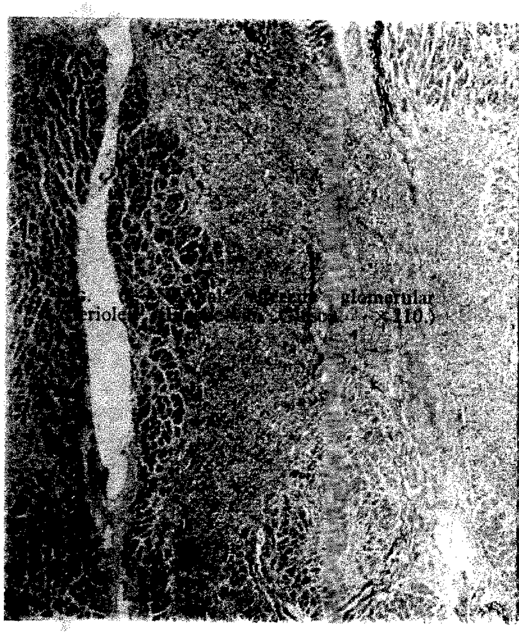

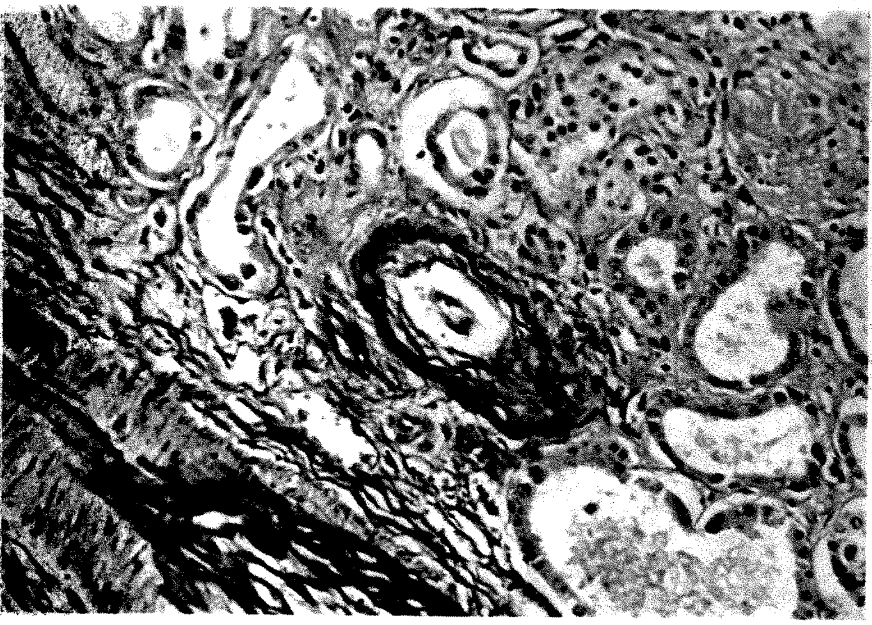

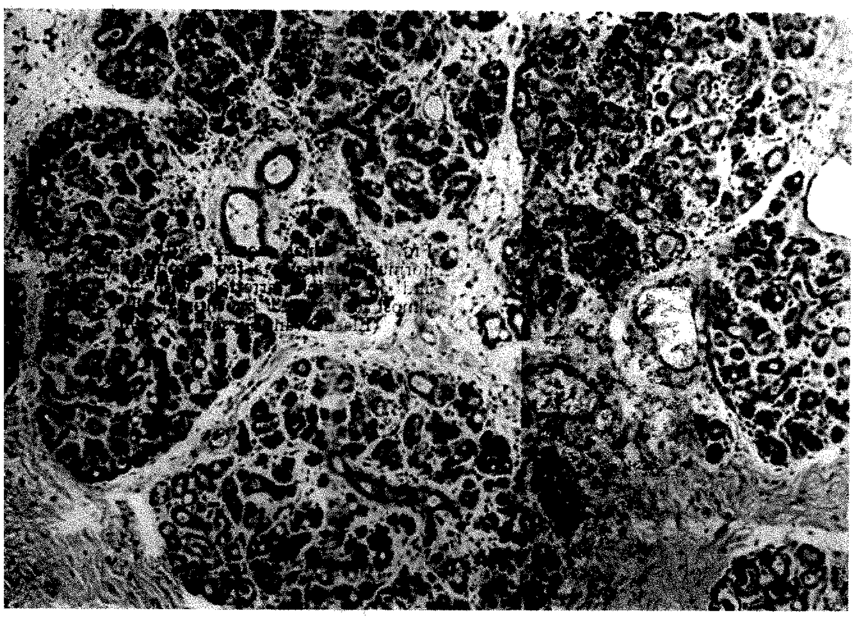

FIG. 7.—Breast tissue showing secretory changes, probably due to chlorpromazine treatment. (H. and E. ×55.)

Pseudomonas pyocyanea, and had to be abandoned on 7 June. She died in uraemic coma on 20 June, six weeks after admission.

Clinical Diagnosis

(1) Oliguric renal failure, with uraemia resulting from either (*a*) malignant hypertension (? essential) or (*b*) polyarteritis nodosa.

Post Mortem Findings

Dr. E. D. WILLIAMS: The body was that of a thin middle-aged woman with a few purpuric spots on the arms and abdomen and slight oedema of the lower legs. There were peritoneal dialysis incisions below the umbilicus and in the left iliac fossa.

The heart weighed 400 g. (normal for patient 286 g.). The pericardium was normal. The left ventricle showed hypertrophy, being 21 mm. thick (normal 15 mm.), but the right ventricle was of normal thickness. All the valves were healthy and valve rings were of normal size. The coronary arteries showed only minimal atheroma without appreciable narrowing. In the basal half of the myocardium of the left ventricle there were numerous small foci (1–3 mm.) of grey tissue replacing the muscle. These were scattered indiscriminately around the circumference. Microscopically these were foci of muscle necrosis (Fig. 2) with fibrous replacement, which varied in age from early organization to full fibrosis (Fig. 3). In some of these foci the microscopic branches of the coronary arteries were occluded by fibrosis, usually together with partial or total destruction of the media. The aorta showed only mild atheroma in the form of fatty streaks and isolated plaques covering less than one-quarter of the surface. The renal arteries were normal, as were the other branches of the aorta.

The *right kidney* weighed 105 g., the *left* 95 g. (normal 115–155 g. each). Their surfaces were smooth, while the cortex was slightly thin and blotchy in colour. There was a small cortical adenoma in the right kidney. Histologically neither of the renal biopsy specimens (Fig. 4) showed more than a few glomeruli, and these were free from any sign of nephritis. There was some evidence of tubular atrophy. The interlobular arteries showed fibroelastosis, while the arterioles showed hyaline change and necrosis. The "onion-skin" intimal thickening of malignant hypertension was not seen. Histological examination of sections of the kidneys taken at necropsy confirmed the presence of tubular atrophy. The glomeruli were free from signs of nephritis and the arteries and arterioles showed the same changes as seen in the biopsy specimens, but in addition a number of arcuate and interlobular arteries did show typical "onion-skin" intimal fibrosis (Figs. 5 and 6). This finding, the lack of renal scarring and shrinkage, and the history of acute hypertensive treatment are consistent with a diagnosis of essential malignant hypertension. Microscopical examination of other arteries showed hyaline sclerosis with occasional points of necrosis in arterioles in the suprarenal, the pancreas, and the heart.

In the abdomen there were fibrinous adhesions between loops of intestine and the omentum, and layers of fibrin over the liver and in the pelvis. Microscopically these showed organizing fibrinous exudate, but few polymorphs and no organisms were seen. The appearances suggested a peritonitis that had been successfully treated. The *parathyroids* were within normal limits, and the *bones* were free from secondary osteitis fibrosa.

Other incidental findings included a few foci of acute pancreatic necrosis, and a few foci of pulmonary alveolar exudate that appeared to be treated bronchopneumonia. There were six mixed gallstones. The *breast* showed lobular hyperplasia and signs of secretion (Fig. 7), possibly due to the administration of chlorpromazine.

Pathologist's Diagnosis

(1) Treated essential malignant hypertension.
(2) Uraemia.
(3) Treated peritonitis with persisting fibrinous exudate.
(4) Focal myocardial necrosis, probably of vascular origin.
(5) Gallstones.
(6) Focal pancreatic necrosis.
(7) Hyperplasia of breast due to drugs.

Discussion

Dr. O. WRONG: One of the chief reasons why we thought she had the histology of malignant hypertension is that in the course of a year she had gone from a stage when her blood-urea level was 48 mg./100 ml. to total anuria with death in uraemia. It is quite likely that at some time during this period she went through a phase of papilloedema with a higher diastolic blood pressure than any we have recorded—particularly in the last month before admission, when she was already ill and stopped treatment. Obviously there must be patients with a condition intermediate between what one would accept as benign nephrosclerosis, on the one hand, and malignant nephrosclerosis, on the other—and she was in this no-man's land, though perhaps more at the benign end of the spectrum histologically, and more at the malignant end clinically.

In the last two years we have had several patients with severe hypertension, progressive renal failure, and the histological features of malignant hypertension who have *not* had a papilloedema. We presume that the malignant hypertension is so rapid that they develop the lesions in the kidney causing uraemia without developing the papilloedema which is usually an accompaniment of the arteriolar lesions. Patients with histological malignant hypertension don't always have papilloedema. I see that Dr. Kincaid-Smith is here today, and I would remind you that in her series of over 200 patients with histological malignant hypertension[1] 3% did not have papilloedema.

Dr. P. KINCAID-SMITH: Yes, I agree.

Dr. WRONG: So we can make a diagnosis of malignant hypertension in a patient who doesn't have papilloedema, particularly if he has got worse rather rapidly. At the moment we have a patient with this syndrome who has actually recovered some renal function after six weeks of dialysis and hypotensive drugs, and has been able to go out of hospital with a blood-urea level of about 200 mg./100 ml. With the patient we are discussing we were not able to persist with treatment for as long as this. I wish we could have gone on longer. Intermittent haemodialysis is probably the best way of treating someone with kidney disease who might have a chance of eventual recovery, but at the time we were not able to squeeze another patient on to our haemodialysis programme, and therefore had to use peritoneal dialysis.

I'm reassured that the infective complications of dialysis were not as bad as we thought they were, but we must do all we can to improve our technique of peritoneal dialysis, in which, at the moment, infection is a limiting factor, as it was here. In this hospital—at least in our unit—we have not so far managed to keep a totally anuric patient alive for more than four months by peritoneal dialysis, because of the technical difficulties caused by low-grade infection. I do find it surprising that this patient had anuria. The glomeruli looked pretty normal, so I presume the blood vessels had closed up completely.

Professor C. C. BOOTH: I find it equally puzzling, frankly, why this patient should have died in oliguric renal failure. I wonder, Dr. Kincaid-Smith, if you would like to comment?

Dr. KINCAID-SMITH: I don't really have much difficulty in understanding the case. I think she had "malignant" hypertension. I believe that she had the lesions in the blood vessels, which I would call treated malignant hypertension; she then blocked off these vessels when she stopped treatment, and became anuric. This used to be fairly common in the course of malignant hypertension—particularly in the days before treatment—and we've seen quite a number of them since treatment has been available. This usually occurs in a patient like this—one who stops treatment, or one who has never been treated. We have done renal biopsies in 80 patients who have been admitted to hospital with acute renal failure and in whom we've expected some sort of irreversible cause; 14 of these have had the vascular changes of malignant hypertension. There are two types of change which are associated with oliguria. The first is the "onion-layering" changes in interlobular arteries. If you follow a particular vessel along they may show definite narrowing in one area and little or none a bit further distally. The second type of change is that the arterioles are quite often occluded by little plugs of thrombosis. This is, I think, thrombotic thrombocytopenic purpura associated with malignant hypertension, and which I think may cause the anuria. I'm very intrigued by the vessels in the heart. I wonder if this had something to do with uraemia rather than hypertension, or whether it couldn't be polyarteritis treated by corticosteroids?

Professor BOOTH: Professor Doyle?

Professor AUSTIN DOYLE: There are one or two things that did occur to me. Dr. Kincaid-Smith has made the statement that if you follow these vessels along you may find obstruction—as far as I know this hasn't been looked for in much detail in this case. Certainly in this kidney there is evidence of ischaemic atrophy. Is it necessary to talk about essential hypertension or benign hypertension? It doesn't seem to me to be a very useful distinction to make. Clearly there are all degrees of involvement of arteries, and clearly this is a patient who has some of the features pathologically of malignant hypertension and some of the features of benign hypertension, but blocked arteries have resulted in her death. I think it is rather uncommon to find these blockages occurring in treated patients, though, as Dr. Kincaid-Smith has said, if treatment is stopped this may happen rather quickly and startlingly.

Dr. C. T. DOLLERY: There are two points worth making. Firstly, the kidney is an organ which requires a high perfusion pressure, so a given degree of arteriolar obstruction will impair the function of the kidney more than other organs. Secondly, I agree with what Professor Doyle has said about the distinction between malignant and benign hypertension. Our work on the retinopathy of Grade III hypertension shows focal damage to the wall of small arterioles, and many people take that as the stigma of malignant hypertension. There is some point perhaps in using the term "accelerated hypertension" to describe this kind of disease. The distinction between grade III and IV retinopathy is still worth while from the clinical point of view, because patients with papilloedema who are treated do a lot worse than those who have only cotton-wool spots.

Professor BOOTH: Why did she get hypertension, then? Were her kidney lesions the primary cause?

Dr. KINCAID-SMITH: Oh no, they were the result.

Dr. WRONG: Why did she get hypertension, then?

Dr. KINCAID-SMITH: I suspect she had it in her genes.

Dr. WRONG: You wouldn't argue that she had toxaemia of pregnancy and became hypertensive on the basis of repeated pregnancies?

Dr. KINCAID-SMITH: She wasn't hypertensive in her first two pregnancies?

Dr. WRONG: Not as far as we know.

Professor BOOTH: Was there any evidence, Dr. Wrong, that this lady had toxaemia in the pregnancy when she *was* hypertensive; did she have proteinuria?

Dr. WRONG: Our evidence is very scanty—we never had any information from New Zealand.

Professor BOOTH: I think it has been suggested that toxaemia of pregnancy may damage the kidney and lead later to malignant hypertension.

Dr. KINCAID-SMITH: Certainly ours would support this—that toxaemic changes may leave permanent damage. I don't know how good the evidence is that it can cause hypertension, because we never really know which came first.

Dr. DOLLERY: Pollock in Chicago has some very convincing serial renal biopsies in a patient who had severe toxaemia. The lesions of the small arterioles have persisted—and even seem to be progressing—though the patient is not hypertensive. It makes one think that hypertension may develop in future.

Dr. C. OAKLEY: Isn't this very unlike toxaemia if she didn't have toxaemia in the first pregnancies? The presence of hypertension in the subsequent ones sounds more like hypertension complicated by pregnancy.

Professor BOOTH: More like a pregnant patient who happens to have hypertension. We are back to Dr. Kincaid-Smith's genes.

Professor J. GOODWIN: Could we come back to the heart again? I would like to ask Professor Harrison whether the vascular changes could possibly resemble in any way the changes described by Saphir and his colleagues[2] in old people who have been given various drugs such as noradrenaline. (I believe this patient had noradrenaline.) They attributed the changes in the myocardium to some sort of hypersensitivity angiitis leading to necrosis. I wonder if this is a possiblity in this patient or whether there were any drugs given that might have done this?

Dr. WRONG: I am afraid I have no information about this. The electrocardiograms showed left-ventricular hypertrophy and non-specific T-wave changes. I'm sorry I can't give you more information.

Professor GOODWIN: Was there left-axis deviation, which might suggest fibrosis of the myocardium?

Dr. WRONG: I don't know.

Professor HARRISON: It is a bit difficult answering this. These changes, where you get a loss of muscle, a falling together of connective tissue, and finally fibrosis are found in patients with aortic regurgitation, or in patients who have had a prolonged period of low cardiac-output failure. The isolated change is common; what is so remarkable in this patient is the enormous number of them clustered together, and of a size that we could see with the naked eye. This is extremely unusual. The next point is the correlation between these and the vascular change accompanying them. Who can tell which is cart and which is horse? If you occlude the vessel surely you might get necrosis of the muscle. If you have dead muscle here are you not in danger of causing thrombosis of the local vessel? I don't know.

Professor GOODWIN: Patients who have massive myocardial fibrosis or necrosis from cardiomyopathy tend to have normal vessels, so I'd have thought the vascular change came first.

Professor HARRISON: That is why I suggested it, but it is impossible to prove it.

Professor BOOTH: Now these vascular changes are thought to produce changes in the red cells. Professor Dacie, would you like to comment on this?

Professor J. V. DACIE: Uraemic patients are often very seriously anaemic. Azotaemia and perhaps infection probably both result in anaemia by diminishing the life-span of the red cells and also by inhibiting erythropoiesis. On top of this we see in some patients—in particular, in those who are suffering from progressive and severe renal failure, often with anuria—a florid haemolytic picture. These patients have a raised reticulocyte count and show fragmented red cells in their blood films. It looks as if a superimposed haemolytic mechanism is active. At necropsy a characteristic finding is disease of small blood vessels of the sort we've seen in the patient we are now discussing. Why the red cells are destroyed is really anybody's guess, but one hypothesis is that they are destroyed in some way by contact with the damaged vessels. Whether this is a result of contact with necrotic tissue, or as the result of intimate contact with fibrin deposited in the vessels, we don't know.

Professor BOOTH: Does this imply that when you see crenated and damaged red cells in the peripheral blood there is fibrinoid necrosis, and that you're therefore dealing with severe hypertension, or accelerated hypertension, or malignant hypertension, or whatever you call it ?

Professor DACIE: We believe this is so, but there are many other causes of this blood picture than malignant hypertension. One such cause is thrombotic thrombocytopenic purpura—or Moschcowitz's disease—where the blood-vessel changes are widespread and not confined to the kidneys. We see, too, a similar picture in cases of carcinomatosis where carcinoma cells are growing in the blood vessels or in the spleen or bone marrow.

Dr. DOLLERY: May I ask a question of our visitors ? What do they think is the difference between benign and accelerated hypertension. If you compare two people with similar pressure levels, one of them may destroy his small arterioles and die with uraemia, while the other goes on for years without suffering severe damage to small blood vessels.

Professor DOYLE: This is a very difficult question to answer There is a good deal of evidence to suggest that the higher the blood pressure the more likely you are to find fibrinoid change and thrombosis in the blood vessels. Another factor is the speed at which these changes develop ; changes rather like this occur rapidly in acute nephritis and in eclampsia. The more rapidly the disease process progresses the more likelihood there is of vascular damage. There is some evidence that it is possible to render blood vessels more sensitive to the changes of high blood pressure. Asscher and his colleagues[3] irradiated the arteries of rats and found increased sensitivity. I don't think an autoimmune factor is beyond the realms of possibility. Evidence for this at the moment is not strong.

Professor BOOTH: Well, I think that's a very clear statement of the present problem.

We are grateful to Professor J. P. Shillingford and Dr. E. D. Williams for assistance in preparing this report, and to Mr. W. Brackenbury for the photomicrographs.

NEW APPLIANCES

A Means of Speaking for Patients with Cuffed Tracheostomy Tubes

Dr. R. M. L. WHITLOCK, formerly registrar, Acute Respiratory Unit, Auckland Hospital, Auckland, New Zealand, writes: Cuffed tracheostomy tubes are used to protect the lower airways in conditions complicated by bulbar paralysis and to facilitate prolonged intermittent positive-pressure respiration (I.P.P.R.) in the treatment of respiratory failure. Patients with these conditions are often unable to write because of paralysis or limb injuries and few people are skilled at lip reading. Because of the need for another means of communication a simple tracheostomy-tube attachment has been developed.

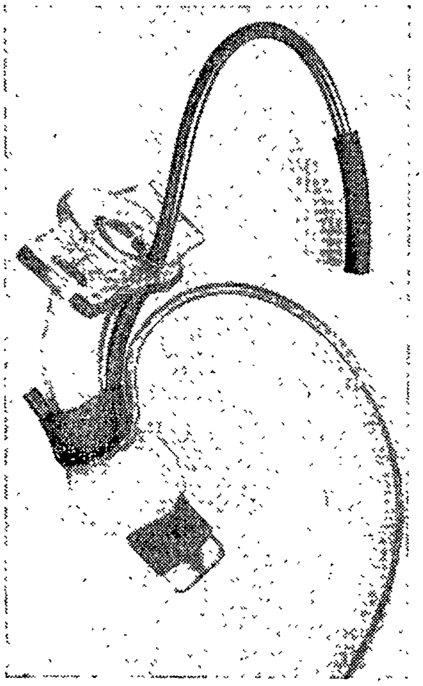

FIG. 1

The attachment (Fig. 1) consists of an F.G. 8 or 10 disposable plastic suction catheter through which air or oxygen is passed to blow on to the vocal cords. The catheter passes through a hole bored in the lower edge of the flange of a Portex plastic tracheostomy tube (Portland Plastics, Great Britain) which has a detachable inflatable cuff at the distal end. It then runs below the tube until it curves round one side to direct the tip upwards towards the vocal cords. Its curved portion is held in position by the edge of the cuff. With the catheter in the correct position (Fig. 2) a gas flow of 5 litres per minute is sufficient for distinct speech in the average adult without discomfort. The supply can be from a small air compressor or an oxygen cylinder with a pressure-reducing valve. To avoid drying of the mucosa and discomfort to the patient it is preferable to warm and humidify the gas, especially if oxygen is used. A pressure-relief valve somewhere in the supply line is a desirable safety measure. The gas supply should not run continuously but only when the patient wishes to speak. If a small electrical air compressor is used the flow rate can be pre-set and the compressor switched on by a microswitch which can be operated by any movable part of the patient's body. Alternatively a nurse may switch on the gas supply.

This attachment is cheap and of simple construction, and does not interfere with tracheostomy management or I.P.P.R. It allows speech throughout the whole of the respiratory cycle, does not rely on I.P.P.R., and has no moving parts. (A specially constructed tracheostomy cannula that uses the patient's exhaled air through a sliding valve for speech has been described elsewhere,[1] but it can be used only for patients on a Bird respirator.)

A delay of three days after tracheostomy is recommended before attempting to use the attachment. This interval allows time for the tracheostome to become sealed by granulation tissue, thus preventing escape of air around the tracheostomy tube or, worse, into the tissues of the neck and mediastinum.

Clinical trials on seven patients have been encouraging with six successes, though one of these found the flow of air too uncomfortable after a successful trial. The failure occurred in a patient with a tracheostome larger than usual which allowed the air to flow out round the tracheostomy tube more readily than through the vocal cords.

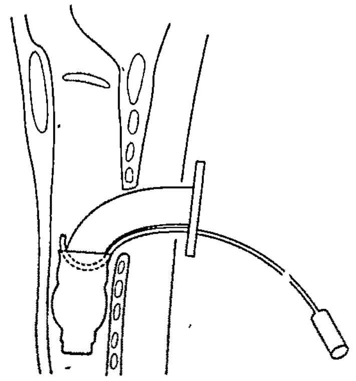

FIG. 2

This speaking-aid not only makes communication easier but also relieves the patient from the frustration and fear of not being able to make his requirements known. There have been no complications from its use.

I thank Dr. M. Spence, medical officer in charge, Acute Respiratory Unit, Auckland Hospital, for permission to develop this device and for advice on its use.

Book Reviews

Conditions Causing Headache

Research and Clinical Studies in Headache. Vol. 1. Edited by Arnold P. Friedman, M.D. (Pp. 221; illustrated. sFr./DM. 41.50.) Basle and New York: S. Karger. 1967.

Interest in the subject of headache has greatly increased in the last decade as research activities move rapidly into the sphere of chemical investigation rather than clinical description, but the literature is so scattered that the average physician finds difficulty in keeping up to date. This book is said to be the first of a series intended to bring together under one cover authoritative reviews on different facets of the problem, and edited by a distinguished physician well known for his own work in this field the series has certainly made a good start. The contributors are drawn from widely separated parts of the world—Europe, Australia, and America—and are recognized authorities on the subjects they discuss. Though any book drawn up in this manner is bound to have a lot of repetition in it, this has been reduced to an acceptable minimum.

The introduction by E. C. Kunkle forms a philosophical prelude, stressing the need to look at the "whole" patient, and often to temper one's therapeutic enthusiasm with sound common sense. It includes a number of classical quotations which will no doubt be a boon to speakers looking for an opening or closing sentence to their discourse on headache. There then follows an extensive review by F. Sicuteri on vasoneuractive substances and vascular pain. This is a valuable article, with 163 references, tracing the development of thought and work on this aspect, and goes well beyond the action of methysergide, the drug with which its author's name has been so closely connected. The clinical use of methysergide is later dealt with by D. A. Curran, H. Hinterberger, and J. W. Lance, from Sydney, who review its development, trials, indications and limitations, and its dosage schedule. It is of course a drug not without dangers, and its most alarming side-effect—retroperitoneal fibrosis—has a chapter to itself written by J. A. Graham and his colleagues from Boston. They analyse 27 cases of this curious condition, which of course also occurs in patients without any such precipitating cause; they consider it in conjunction with other types of inflammatory fibrosis (for example, pleuro-pulmonary fibrosis) occurring during methysergide therapy and think the drug uncovers rather than causes a predisposition to collagenosis in susceptible individuals. They suggest further that more attention might be paid to a possible link between migraine and the collagen disorders.

A very useful clinical chapter on migraine variants is contributed by J. D. Carroll, but this is marred a little by some unfortunate phraseology and even some inaccuracies. The statement that in recurrent attacks of unilateral headache followed by a third nerve palsy, or sometimes a total unilateral ophthalmoplegia, arteriography has always failed to show any abnormality could be very misleading to many readers, and this is not helped by the later statements that the most common sites for aneurysms causing the ophthalmoplegic variety of migraine are the main trunk of the internal carotid artery or its junction with the posterior communicating artery. Most neurologists and neurosurgeons will know what the writer means by these apparently contradictory statements, but there are many others who are going to read this book. This section also quotes another author as holding views on certain arteriographic appearances in "ophthalmoplegic migraine" which are exactly the opposite to those which he has published, and it is a pity that this has been allowed to creep into a textbook.

There is a chapter by R. Greene on menstrual headache, and a justifiably rather indefinite chapter by P. F. A. Hoefer on the electroencephalogram in headache. The book ends with two chapters from the Mayo Clinic by M. J. Martin, H. P. Rome, and W. M. Swenson on that most common of all chronic headaches—the muscle tension headache—which is so often glossed over in a few sentences in textbooks. Here it is looked at symptomatically, aetiologically, and therapeutically. The optimism of two of the authors in the results of treatment will not be shared by many, and it is important not to confuse relief from the headache with relief from the patient's complaints about it. However their emphasis on looking at the patient as a whole brings us back to the introduction and so rounds off a most informative book, which will be a source of reference of great value to anyone trying to understand the wide spectrum of the conditions causing headache.

EDWIN R. BICKERSTAFF.

Philosophical Approach to Learning

An Introduction to Gynaecology and Obstetrics. By Philip Rhodes, F.R.C.S. (Eng.), F.R.C.O.G. (Pp. 278+viii; illustrated. 21s.) London: Lloyd-Luke. 1967.

The plethora of small books on obstetrics and gynaecology which have been added to the collection of new editions of old-established small textbooks of the "crammer" type in recent years would seem to make it very difficult to justify the production of yet another. This is a textbook with a difference, as it approaches the subjects in a novel fashion and is obviously not intended as a book for quickly memorizing a few essential facts before an examination as are so many of the other small textbooks.

The author deals with the subject in an almost philosophical fashion, and has tried, with success, "to show something of the background ideas which inform the practice of gynaecology and obstetrics." He has also succeeded in bringing into perspective the relationships between obstetrics and gynaecology and the other disciplines of medicine. This has been difficult to achieve in the compass of the small size of this book while still introducing all the essential factual elements of obstetrics and gynaecology. It is not intended to replace a full textbook, but a student reading this book would be able to grasp the wider concept which Professor Rhodes has been trying to convey. When a student comes to reading any of the present large textbooks, particularly if they are being used only for reference, after reading this small book he will be able to see any of the conditions found in obstetrics and gynaecology in its true context in relation to medicine. In any new venture there are bound to be some parts which are not universally acceptable; for example, it might have been preferable to deal with the treatment of each condition as it occurred rather than to leave the whole treatment in gynaecology to one chapter. This is a small criticism of a book which is otherwise very attractive, both from the point of view of what it is aiming to do and for the way in which the author expresses his undoubted literary ability.

This book can certainly be recommended to students in preference to all the other books on obstetrics and gynaecology which some students rely on without reading one of the large textbooks, because this book, while small, does not attempt to provide more than a framework but does convey an impression of the width and scope of the subjects of obstetrics and gynaecology.

IAN MACGILLIVRAY.

Human Extracellular Proteins

Molecular Biology of Human Proteins. Vol. 1. Nature and Metabolism of Extracellular Proteins. By H. E. Schultze and J. F. Heremans. (Pp. 904+xii; illustrated. £15.) Amsterdam, London, and New York: Elsevier. 1966.

On opening a book of this size one expects to find a collection of articles lacking coherency and of varying quality that have been contributed by a group of authors. It is a refreshing surprise to discover that this massive book has been compiled by two authors, that it possesses many of the desirable qualities which should be associated with single- or dual-authorship, and that it contains a critical, concise, and comprehensive account of interwoven topics.

This volume represents the first half of a treatise on the soluble proteins of human plasma and other extracellular fluids, and in particular on the understanding of. their physiological activities in terms of their molecular structures. The title of the treatise is, however, somewhat optimistic, since the relationships between the structures of the majority of the proteins which are discussed and the functions of these proteins in health and disease have yet to be elucidated. The book is divided into four sections: (1) a survey of protein structure and of physical, chemical, and immunological methods of analysis; (2) tables of the properties of thirty-four purified plasma proteins and a survey of the methods which are used to fractionate plasma proteins; (3) an account of the biosynthesis and metabolism of plasma proteins, including the exchange of the proteins between mother and child; and (4) a description of the nature and properties of the proteins of extravascular secretions. The text is supported by extensive tables, over 400 illustrations, numerous references, and a subject index. Although much of the information presented in the first section is available elsewhere in greater detail, the remaining sections contain material which has not previously been published collectively in such detail. Each topic is developed historically from the first significant observations to the beginning of 1965.

However, science does not stand still while books are printed, and much new information on, especially, the structure of proteins and, in particular, of the immunoglobulins has appeared since this volume was written. But, in spite of some of the topics being a little behind the times, this book will be invaluable to all who are interested in the nature, biosynthesis, and metabolism of the proteins of human extracellular fluids.

M. J. Crumpton.

Systems of Medical Care

Medical Care. Social and Organizational Aspects. Edited by Leslie J. DeGroot, M.D. (Pp. 538+xiv. $16.50.) Springfield, Illinois: Charles C. Thomas. 1966.

This book is chiefly a collection of papers on medical care in the United States which appeared in the *New England Journal of Medicine* from 1963 to 1964. New information has been added, together with several additional papers.

Of the 36 chapters 35 are contributed by American experts. Chapter 23, on the regionalization of hospitals in the United Kingdom, which is written by Dr. John R. Ellis, secretary of the Association for the Study of Medical Education, is useful for comparison with American systems.

The first chapter, "Twentieth Century Attitudes towards Health," quotes a nation-wide survey which concluded that "the overwhelming majority of Americans seem to have a deep respect for the personnel, facilities, and services provided by modern medicine."

It is interesting to note that, as in Britain, in the 1930s the support of hospitals by private wealthy donors ceased in America. These are now chiefly supported by private repayment insurance and grants from governmental bodies. More persons obtain medical care, and there is an increasing demand for good care. Chapters 2 to 8 discuss selection of medical students, undergraduate and post-graduate medical education, and integration of education with medical research. Chapters 9 to 15 deal with community, university, and voluntary teaching hospitals and nursing-homes in their various aspects and their relation to social medicine. Chapter 16 critically compares health-service systems in the United States with those of other countries, especially Sweden and Great Britain. Chapters 17 and 18 are concerned with the general practitioners and group medical practice. Chapters 19 to 27 touch on many problems of hospital and health planning and medical care. Chapter 26, on public medical care for the needy, indicates that the provision is uneven, and still is based on the Poor Law principle, which Great Britain began to abandon in 1929. Chapters 28 to 35 are devoted to further medical organizations and features of medical care. In Chapter 30 there is an excellent account of the aims and work of the American Medical Association. As is well known, the administrative organization of American public health is of a high standard (see Chapters 25 and 28). Several of the contributors to this book suggest that it should be more closely integrated with the clinical medical services.

Finally, in Chapter 36 the editor, Dr. L. J. DeGroot, considers that in the future the Federal Government will organize medical care on a comprehensive scale. It may well be so, but in so vast a country as America, composed of a number of States with their own laws and regulations, often differing from one another, it will be a gradual and prolonged process.

Dr. DeGroot has essayed a difficult and controversial subject for this book. He and his contributors have done it well, though inevitably there is much repetition and overlapping and some disagreement in so wide a symposium.

Arthur S. MacNalty.

Blood Groups

Lehrbuch der Menschlichen Blut- und Serumgruppen. 2nd edition. By Professor Otto Prokop and Dr. Gerhard Uhlenbruck. (Pp. 924+xvi; illustrated. £6 13s. 7d.) Leipzig: Georg Thieme. 1966.

In the introduction to the first edition of this textbook on blood and serum groups the authors stated that they were closing some gaps by adding to the discussion of blood groups in general a more detailed account of the modern serum groups and of the chemistry of blood group substances. A second edition became necessary within less than three years, and this has now become a handbook rather than a mere textbook. It has become impossible to cover the whole field because it now includes molecular biology, immunochemistry, and serological genetics. It helps, therefore, that at the end of this second edition there is a list of international addresses of experts in many fields. There are several hundred names, but only for some of them do the addresses indicate the expert's special interest. Many of the names, of course, speak for themselves, but nevertheless it is often not easy to know what kind of help the person indicated may render. There is also an enormous list of references, 142 pages with some 30 references per page. Another interesting feature is a table giving the dates of the discovery of 82 blood group systems, with the names with which they are associated, beginning with the ABO groups discovered by Landsteiner in 1900. It ends with three blood groups discovered in 1965: Kamhuber, A_{hel}, and Do^a.

The blood groups themselves are described and the preparation of antisera in various animals is discussed. There is an excellent and detailed chapter on the chemistry of blood group substances. Haptoglobins are described, and methods for their recognition such as starch electrophoresis using various buffer systems are given in detail. The pre-albumins, the Gm and the Gc and the Ag serum groups, as well as the cholinesterases, are given a chapter each, and there are chapters on the qualifications of blood group experts for law cases and on the probability calculations for eliminating paternity. There is a very detailed description of the present position of the association of blood groups with diseases. This is an excellent book, but it will be appreciated only by readers who are fully familiar with the German. However, even those who may find the language occasionally difficult may learn from its unique collection of references.

H. Lehmann.

Value of Group Treatment

The International Handbook of Group Psychotherapy. Edited by J. L. Moreno, M.D. (Pp. 747. 84s.) London: Peter Owen. 1966.

In July 1963 the Third International Congress of Group Psychotherapy met in Milan. One hundred and twenty-four papers were read in five different languages. All the papers have been collected and are presented in this voluminous tome in their original language and usually in highly abridged form.

The master mind behind the Congress and the main editor of the book is J. L. Moreno. He does not let this opportunity slip without reminding us, once again, of his unique contributions to the initiation and development of the theory and practice of group psychotherapy. He confides that he began it all in 1913 with some prostitutes in the sexual ghetto of Vienna. Since then he has come to see in group therapy a "third psychiatric revolution" whose "ultimate goal is a therapeutic society, a therapeutic world order." Moreno believes that it is his role to spread the gospel of group treatment. He is supported in this belief by his wife, who contributes the longest paper to the book. She disavows "misplaced modesty," and says of her husband: "Like a modern St. Paul, Moreno . . . carried the message everywhere." This book is certainly a monument to his achievement in establishing an international group therapy movement.

To those in search of evidence of the value of group treatment, or of the differential merits of particular modifications of it, this book has little to offer. But those who need no further convincing will find a rich feast in it of theoretical formulations, technical variations, diversities of applications, and range of methods used in the teaching and training of novices. It is indeed remarkable to see how much thought and ingenuity have gone into the interpretation of group processes, the development of new practices, and the discovery of new fields of usefulness.

Life Insurance

Annals of Life Insurance Medicine. 1967. Vol. 3. Edited by Swiss Reinsurance Co., Zurich. (Pp. 272; illustrated. DM. 42.) Berlin, Heidelberg, and New York: Springer. 1967.

The title of this book might lead one to believe that it is of interest only to actuaries and medical advisers to life insurance offices, and the first article, which is concerned with the interpretation of survival rates, and which contains a liberal sprinkling of mathematical symbols, certainly confirms this impression. But the persistent reader will eventually be rewarded by finding something of interest among the remaining 14 articles which make up the book.

There is, for example, an interesting chapter on variations in mortality rates and causes of death in different parts of the world. This is followed by a well-documented article on the antecedents of disease based on the records of a number of North American life insurance companies. By relating the results of medical examination of persons accepted for life insurance to their subsequent survival these studies provide some assessment of the significance of variations in body build and blood pressure and of such abnormalities as heart murmurs and arrhythmias, chest pain, albuminuria, and glycosuria. Some of these points are developed by other authors, who contribute articles on the value of the electrocardiogram, the prevalence of silent coronary disease, and the significance of heart size and of proteinuria.

Most of the rest of the book deals with matters which one does not usually associate with life insurance medicine. These include the results of valvuloplasty for mitral stenosis (first presented in 1962 and now looking a little dated), the prognosis of chronic cor pulmonale, the pathogenesis and course of stroke, the prognosis of haemorrhagic diseases, and the aetiology of diabetes and its long-term prognosis.

With such a variety of content this book might reasonably be expected to have some appeal to physicians, epidemiologists, medical statisticians, and of course those concerned with life insurance methods. But few readers are likely to find so much of it useful that they would hasten to buy it. It is perhaps a book more for the library shelf than for one's own bookcase.

R. G. RECORD.

Sigerist, Medical Historian and Diarist

A Bibliography of the Writings of Henry E. Sigerist. Edited by Genevieve Miller. (Pp. 112+vi. $6.00.) Montreal: McGill University Press. 1966.
Henry E. Sigerist: Autobiographical Writings. Selected and translated by Nora Sigerist Beeson. (Pp. 247+xii. $5.75.) Montreal: McGill University Press. 1967.

Two important books dealing with the life and works of Henry Sigerist, the leading medical historian of his time, have been published by McGill University Press, Montreal. Each is complementary to the other, although the autobiography may have the wider appeal.

The bibliography, prefaced by a brief account of Sigerist's life-work by Professor Ackerknecht, of Zurich, consists of a list of books, papers, addresses, and reviews, 520 items in all, each dated, annotated, and indexed. Two outstanding entries are volumes I and II of the eight-volume *History of Medicine* which Sigerist had planned and begun only a few years before his death in 1957 at the age of 66, and which remained unfinished. Among his earlier books, *Socialized Medicine in the Soviet Union,* and *Civilization and Disease,* though subjected to much controversy, exercised a widespread influence.

For the general reader, the second of the two books under review may be of greater interest. Entitled *Autobiographical Writings,* it supplies a clear picture of the life and work of a remarkable man. In 1953, only four years before his death, Sigerist began to write his autobiography, which, unfortunately, goes no farther than his childhood in Paris and his schooldays in Zurich. From his notes and diaries, however, his daughter, Nora Sigerist Beeson, has been able to complete the picture in her father's own words dating from 1910, when, as a student in Zurich, he discovered that "medicine was the most fascinating of academic subjects." In 1919 he met Professor Karl Sudhoff, who had created an Institute for the History of Medicine, and in 1925, at the early age of 33, he succeeded Sudhoff in the chair of medical history, at that time regarded merely as "a delightful hobby for retired practitioners." Sigerist remained at Leipzig until 1931, when he was called to America to succeed W. H. Welch (the famous "Popsie" Welch) in the medical history chair at Baltimore. From that critical point in his career the autobiography is a series of extracts from the diaries which record his activities until 1947, when he retired from the chair and went to live in Switzerland, where he died ten years later. His Swiss home, "Casa Serena," Pura, was a remote retreat which became a Mecca for medical historians.

"To write a diary," Sigerist tells us, "is to stop each day, to think of what one wanted to do, and of what one did not do: the effect is very salutary." Little did he imagine that his diaries would one day appear in print, and that his comments, so helpful and so human, might even influence future generations. Is it a wild surmise, or only wishful thinking, to suggest that Sigerist may one day earn a place among the great diarists of literature? Certainly he achieved greatness as a scholar, and as a real friend to many, and his service to medicine was invaluable.

DOUGLAS GUTHRIE.

Books Received

Review is not precluded by notice here of books recently received.

Renal Transplantation. 2nd edition. By Roy Yorke Calne, M.A.(Cantab.), M.S.(Lond.), F.R.C.S.(Eng.). (Pp. 220+ix; illustrated. 63s.) London: Edward Arnold. 1967.

New Drugs. Evaluated by the A.M.A. Council on Drugs. 1967 edition. (Pp. 390+xiii. $3.50.) Chicago: American Medical Association. 1967.

Die Tollwut bei Mensch und Tier. By. Dr. Claus Eichwald and Dr. Horst Pitzschke. (Pp. 300; illustrated. £3 4s. 11d.) Jena: Gustav Fischer. 1967.

Klinische Chirurgie für die Praxis. Ergänzungs- und Registerband. Edited by Professor O. Diebold, Professor H. Junghanns, and Professor L. Zukschwerdt. (Pp. 300+ix; illustrated. DM. 74.) Stuttgart: Georg Thieme. 1967.

Die Pulmonale Hypertension bei Angeborenen Herzfehlern im Kindesalter. By K. Bühlmeyer. (Pp. 89; illustrated. sFr./DM. 22.) Basel and New York: S. Karger. 1967.

Morceaux Choisis sur les Rhumatismes Inflammatoires Chroniques de l'Enfant. By N. Bloch-Michel *et al.* (Pp. 260; illustrated. 40 F.) Paris: L'Expansion Scientifique Française. 1967.

Olduvai Gorge. Vol. 2. The Cranium and Maxillary Dentition of *Australopithecus (Zinjanthropus) boisei.* By P. V. Tobias. (Pp. 264 +xvi; illustrated. 90s.) London: Cambridge University Press. 1967.

The Haemolytic Anaemias. Congenital and Acquired. Part 3. Secondary or Symptomatic Haemolytic Anaemias. 2nd edition. By J. V. Dacie, M.D., Hon.M.D., F.R.C.P., F.R.S. (Pp. 719–991+vi; illustrated. 60s.) London: J. & A. Churchill. 1967.

Proceedings of the World Population Conference. 1965. Vol. 2. Fertility. Family Planning. Mortality. (Pp. 510+xiii. $7.50.) New York: United Nations Department of Economic and Social Affairs. 1967.

Lectures to Relatives of Former Patients. By Abraham A. Low, M.D. (Pp. 229. $5.00.) Boston, Mass.: Christopher Publishing House. 1967.

Synopsis of Pediatrics. 2nd edition. By James G. Hughes, B.A., M.D. (Pp. 1099+xvi; illustrated. 82s.) London: Henry Kimpton. 1967.

A Textbook of Sex Education. By Dr. Julia Dawkins. (Pp. 98+v; illustrated. 15s.) Oxford: Basil Blackwell. 1967.

Transactions of the Association of Life Insurance Medical Directors of America. Vol. 50. Edited by Samuel R. Moore, jun., M.D. (Pp. 362+x. No price given.) Boston, Mass.: Association of Life Insurance Medical Directors. 1967.

The Clerkenwell Riot. The Killing of Constable Culley. By Gavin Thurston. (Pp. 188+xv; illustrated. 28s.) London: George Allen & Unwin. 1967.

Invertebrate Nervous Systems. Their Significance for Mammalian Neurophysiology. Edited by C. A. G. Wiersma. (Pp. 370+x; illustrated. 72s.) London: University of Chicago Press. 1967.

The Origin of Life. By J. D. Bernal. (Pp. 345 +xvi; illustrated. 55s.) London: Weidenfeld & Nicolson. 1967.

OUTSIDE EUROPE

Medicine in Burma Today

A. W. WOODRUFF,* M.D., PH.D., D.T.M.&H., F.R.C.P., F.R.C.P.ED

Brit. med. J., 1967, **3**, 551–554

Very great developments have taken place in Burma, and particularly in the medical services in Burma, over the past two decades, and a new administrative organization of these services was inaugurated on 1 January 1965. Little has been heard of these developments in Britain or elsewhere, yet they are remarkable and important. Remarkable in that they have been carried out without any considerable amount of external aid and in this way differ fundamentally from those which have taken place in Africa. Important in that very great emphasis has been given to taking medical services to the people in rural areas, an aim which has defeated the health administrators of many tropical countries. It is important, too, that these developments should be known; there are many lessons to be learned from them and there may be some opportunities for co-operation in furthering them. The opportunity recently arose to see something of these developments, and some of the changes that have occurred in the country during the past 20 years, when I was invited to Rangoon by the Burma Medical Association and to participate in its Annual Meeting.

First a word about why comparatively little is known of these developments outside of Burma. The short answer is, of course, that in recent years Burma has been relatively isolated; the passionate and understandable desire which the Burmese have for complete independence led them to leave the Commonwealth and, as a corollary to this, to make themselves ineligible for aid extended to Commonwealth countries. Likewise, in 1953 Burma terminated the arrangements which they then had for aid from the United States Government. The precipitating factor here was involved with the now almost forgotten Chinese Nationalist invasion of Burma at that time and the evidence that aid to these invaders was coming from American sources. There were various other reasons for the termination of the arrangements with the U.S.A., principal among which being an intense desire on the part of the Burmese people to avoid any help, no matter how desirable, if conditions were attached to it. This is mentioned as a matter of record; the purpose is to present some of the factors which enable us to understand the background to current developments in Burma and the reasons why these are proceeding with a minimum of outside aid. No doubt material developments could have taken place more rapidly had large-scale aid been accepted, but this desire for independence, so passionately cherished by the Burmese people, who prefer to develop along individual lines, is something which has won widespread respect. They, like everyone else, realize that South-east Asia is now and for some time has been in a highly inflammable state and they have no wish to become another Vietnam. Their country has in the last 20-odd years been torn by war several times, first in operations against the Japanese, then by civil war which continued in places until about 1960 and which was aggravated by the Chinese Nationalist invasion between 1950 and 1954, an invasion which came within 20 miles (32 km.) of the important town of Taunggyi in central Burma. A result is that only recently have they begun to see the end of a phase of national reconstruction.

Colour, Gaiety, and Hospitality

In reconstructing their country after all this trouble the Burmese people have a great desire to weave all that is best of their ancient culture into national development in its modern sense. This finds expression in the encouragement being given to traditional Burmese opera, of which there are schools in Rangoon and Mandalay. Burmese opera is certainly a fine art in the true sense of that term as meaning that skilful execution is aimed at as an objective in itself. It is not an art form which has been subjugated to propaganda purposes, and, in keeping with the Burmese national character, it is extremely colourful. Indeed, gaiety and a capacity for friendship and hospitality are outstanding characteristics of the Burmese, and colour is one of the most striking characteristics of the country.

This desire for colour is of course very obvious in the dress of the tribespeople from around the periphery of Burma. As we all know, there have been differences of opinion between these groups and the central government, and the present aim is to bring about their integration with the peoples of Burma proper. With this object a school for national groups has been established at Sagang, and here selected young persons are brought together for periods of a year and trained in local government, so that on returning to their homes they will be able to take a prominent part in running local affairs. I visited the Academy, and certainly they were an exceedingly happy group obviously getting on well together.

Thriving Teak Industry

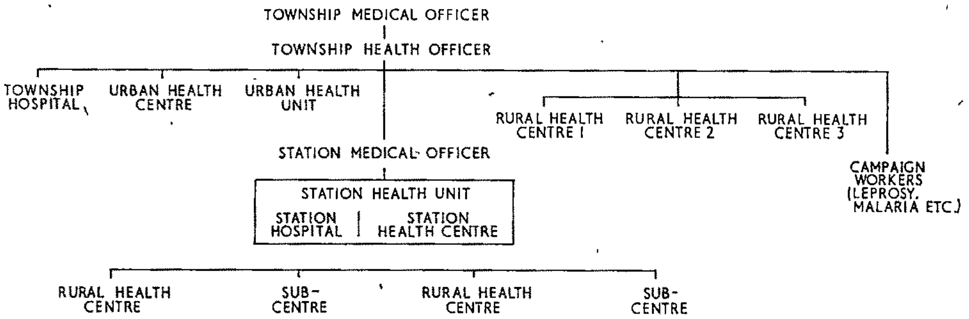
The Ava Bridge, near Sagang, partially destroyed in the last war, has been repaired, and some years ago was reopened. There was evidence near by that the teak industry is thriving, and there were many very large rafts of teak logs temporarily halted at Sagang on their way down the river. I was informed that exports of teak have surpassed their previous level and that a large demand for it has been created by the recently introduced improved processes for veneering cheap woods, such as pine, with teak.

Reconstruction of the Health Services

Regarding the magnitude of the task of reconstructing and developing medical services in Burma it must be remembered that, unlike India and the countries of Africa, building up after the last war had to begin from a medical service which had virtually collapsed during the Japanese regime. A major factor at that time had been the departure from Burma of large numbers of doctors and health auxiliaries on which the health service had mainly depended. To quote Tinker (1961), "Rangoon became a vast slum following the breakdown of the public services and the influx of thousands of refugees who erected basha huts in the main streets and in all open spaces. Everywhere malnutrition was widespread, malaria was rampant, not one vaccination was carried out after 1941, and there were several smallpox epidemics." Though the framework of the medical service was quickly re-established after the cessation of hostilities much that had been damaged could not be speedily restored; to take but one example, the vaccine depot at Meiktila had been razed to the ground, and, with the organization built around it, could not be readily replaced. Similar destruction elsewhere, together with the subsequent civil war, has meant that development in Burma has gone on slowly, with dependence on imported supplies to a much greater extent than in most other countries.

---

* Wellcome Professor of Clinical Tropical Medicine, London School of Hygiene and Tropical Medicine; Physician, Hospital for Tropical Diseases, London N.W.1.



Reorganized administration arrangements. (From *Burma Medical Journal.*)

The reorganized health services as inaugurated on 1 January 1965 are noteworthy in that they have been moulded with the aim of extending their frontiers to the rural workers and farmers, and a particularly important point is that preventive and social medicine is to be based at hospital centres. These preventive and social services will not form, as elsewhere, a separate organization divorced from clinical work. There is also to be complete unification of health services both of Burma proper and of the states, and the health services of the central government and the local administrative services have been merged into one.

Township Medical Officers

Burma has now a population of approximately 23 million and is served by 2,100 doctors—that is, one doctor for 11,000 inhabitants. A key person in the reorganized medical service is the township medical officer. He represents the Director of Health Services at the township level; he will have at least one additional medical officer under him even in the smallest township, and there can be as many as ten or more in the larger towns. The township medical officer, with the assistance of other medical officers and staff, will be responsible for all the functions of the health department in his district, both curative and preventive. In most cases he will be a doctor with general medical training, along with training in preventive medicine. The organization is as set out in the Chart, which is adapted from KoKo (1965).

Hlegu.—The population covered by the township medical officer will be variable, but one that I visited was at Hlegu, and is representative of the pattern. Here the town itself has some 10,000 people, and the district around it which the centre serves has approximately 60,000. The urban centres function mainly as general practitioner units. The station medical officer in this particular set-up was located at Phaunggyi, some 17 miles (27 km.) distant from the township of Hlegu. He was in charge of a new station health unit comprising a small hospital of 16 beds with an attached health centre. From such a station health unit there are normally to be run some four to six rural health centres staffed by health assistants, health visitors, or midwives. In other places rural health centres may not be run directly from a station health unit. Attached to an organization such as this there are the various campaign workers. The township of Hlegu was, for example, in the attack phase of the national malaria eradication programme. The kinds of diseases dealt with at this township hospital are shown in the Table. There are two main wards, a medical and a surgical, and a total of 50 beds. A small laboratory of the clinical sideroom type is equipped with a microscope and some simple reagents. In all the hospitals which I visited I was struck by the number of patients with amoebic dysentery and its hepatic complications, and this small hospital was no exception. The township of Hlegu is approximately 30 miles (48 km.) from Rangoon, and on the way to it one passes Taukkyan, one of the several British war cemeteries in Burma; this one, beautifully maintained, contains approximately 20,000 graves. On the stonework of the colonnade in the background are recorded the names of some 27,000 soldiers who died in the campaign in the last war in Burma or Assam but whose bodies could not be found or identified.

Admissions to Hlegu Township Hospital

	1965	Range 1961–5
Trauma	106	
Pneumonia	52	
Pulmonary tuberculosis	46	9–66
Intestinal helminths	39	39–723
Malaria	35	35–73
Beriberi	29	
Anaemia	28	
Snake-bite	26*	
Bacillary dysentery	21	1–131
Amoebic dysentery	17	3–132
Typhoid fever	13	2–13
Others	648	
Total	1,060	

* Including 3 who died.

Divisions

The country is at present divided into six divisions—Rangoon, Central, North-west, South-west, South-east, and Eastern. Later these will be subdivided to make nine. The divisions contain variable numbers of townships with their associated hospitals and organizations, and each division contains variable numbers of district hospitals. An example of one of these is the new General Hospital, Taunggyi, which has recently been completed and has 200 beds. Taunggyi is a town of 40,000, and is the capital of the Shan states, in which 2.2 million live. From most of central Burma malaria has now been eradicated, and it has disappeared from Taunggyi.

Co-operation between Military and Civil Medical Services

A great deal of co-operation takes place between the military and the civil medical services in Burma, and this is exemplified by the arrangements existing at Maymyo. This town of approximately 60,000 inhabitants has a civil hospital of 180 beds and the base military hospital of Northern Command, Burma, of 500 beds. Patients needing special treatment are transferred from the civil hospital to the military hospital. Here are five divisions—medicine, surgery, obstetrics, dentistry, and paediatrics—and eight specialists in charge of the main divisions plus sections of pathology, anaesthetics, and ophthalmology. Diseases of particular interest encountered here include, in addition to the dysenteries and some imported malaria, approximately 15 cases of mite typhus per month. When I was there towards the end of January they had had 30 cases in the previous two months. Here as at Taunggyi many liver abscesses are dealt with; there had been six in the six weeks preceding my visit to the hospital. They had also had six proved cases of typhoid in the previous year. A good deal of leprosy occurs; they had 60 cases in the hospital when I was there, and approximately 40–50 new cases are seen per year.

Workers' Hospital

There are various other hospitals below the teaching hospital level, and among these is the new Workers' Hospital in Rangoon. This has 200 beds, and is a very modern and well-equipped institution. It is outside the health services, being run by the Ministry of Labour, not the Ministry of Health, and is open to those who join a contributory scheme. It has five whole-time specialists—one each in medicine, general surgery, obstetrics, ophthalmic disease, and anaesthetics. There are 1,500 deliveries a year in the hospital, and it is of particular interest that about 100 patients suffering from liver abscesses are seen annually.

Teaching Hospitals

Mandalay

There are now medical schools at Mandalay and Mingaladon in addition to Rangoon proper. At Mandalay the school was opened in 1955 and now has three groups of graduates. The teaching hospital, until a new one is built, is the long-established Mandalay General Hospital. The accommodation is adequate, perhaps not more than adequate, and ancillary services are well established. Much of the preclinical accommodation is in a converted school. There are 50 graduates annually. A certain amount of new building is taking place; the preclinical buildings include some that are new and others that have been adapted from a school. The nurses have a very fine new building, and more building is to follow.

I was interested to learn that kwashiorkor is a common disorder in and around Mandalay. The scientific importance of its occurrence is increased by the fact that there is no malaria in the region now, and in the children with kwashiorkor helminthic infection is not a problem, so that the absence of these two infections—both of which in Africa are sometimes thought to precipitate an attack of kwashiorkor—suggests that that disease is more certainly the result of a pure nutritional deficiency in some and a deficiency with superadded bacterial or viral infection in others.

McRobert (1966) commented on the contrast between utilization of medical women in Britain and in Asia, and stated that "the education of medical women was one of the best things we did in Asia." In this connexion it is of interest to note that, whereas in Britain there is only one woman professor of general medicine among 27 medical schools, in Burma there is one from Mandalay among three medical schools, the one being Professor Daw Myint Myint Khin.

Leprosy.—A leprosy control project was started at Mandalay in 1958 and has become the base from which control throughout the country is very largely organized. There are approximately 140,000 patients with leprosy in Burma—that is, 6 per 1,000—and of these 25% have the lepromatous variety; when the project started there were 210,000. The World Health Organization is helping with this control project. Patients are treated in their homes, and admission to hospital or institution is reserved for those who are seriously ill. In each project area one doctor, two leprosy inspectors, and approximtely 30 paramedical personnel are employed. There are now 30 such areas. These paramedical personnel "dig out" the patients, visit them, and deliver the drugs personally and see that they are taken. The staff of 30 project areas are entirely Burmese with the exception of two members of W.H.O. personnel. In these project areas the survey is carried out in three parts. The first part is limited to established patients, whose treatment is organized and assured, and the second part comprises all schoolchildren in the project area and all known contacts; patients found in this way to have leprosy are rapidly brought under treatment. The third stage of the survey is then entered upon, and everyone in the project area is examined. It is found that even with the most assiduous industry in stages one and two, approximately 30% of those who have leprosy will be missed unless the third stage is carried out. The W.H.O. project leader, Dr. F. Noussitou, with whom I discussed this work, told me that because of the arduous nature of the duties and of the close co-operation required from the local population, comprehensive leprosy control and eradication of this kind has either failed or been only a partial success in every other country in which it has been tackled. However he, an Argentinian, was high in praise of both the quality of the Burmese staff with whom he had been provided and of the co-operation of the local people, the result of this combination being that the scheme was regarded by the World Health Organization as highly successful.

Many who have been to Mandalay will be pleased to know that the extensive war damage to the fort and to Pagoda Hill has now been completely repaired.

On the way from Mandalay to Rangoon by air there was an opportunity once again to see Mektilla, which at the end of the last war was extensively damaged but which has now been entirely reconstructed.

Medical Schools at Rangoon and Mingaladon

At Rangoon and near-by Mingaladon there are the remaining medical schools in Burma.

The Mingaladon School, named the Number 2 Medical Institute, Burma, was opened only in June 1963. The preclinical buildings are all new, are well equipped, and have a very good library. There is an intake of 50–60 students per year. The teaching hospital associated with the medical school is the much-expanded Defence Services General Hospital, Mingaladon.

Institute of Medicine No. 1 Rangoon and the Rangoon General Hospital

This hospital has been expanded from 750 to 1,400 beds since the end of the war, largely by converting the basements and parts of the somewhat spacious verandahs into wards. The eye, the ear, nose, and throat, the tuberculosis, and the children's sections have been moved out of the main hospital into special hospitals of their own, only some emergency work in these fields being done at the General Hospital. Many special units have been set up, including neurosurgery, thoracic surgery, urology, orthopaedics, hand surgery, plastic surgery, a leprosy reconstruction unit, a cancer unit, and a cardiological unit.

The Burmese medical qualifications have recently been accorded full recognition by our own General Medical Council.

The expansion of the hospital and preventive medical services has caused a very great increase in the demand for paramedical personnel, and this demand is being met by the construction of a fine new school for such personnel. It is located in the grounds of Rangoon General Hospital, so that the full facilities in the hospital will be available to the trainees.

Burma Medical Research Council and Institute

The Burma Medical Research Council was founded in October 1962 with the aim of improving the health of the people, of advancing medical and allied sciences through research, and of the co-ordination of work in medicine and of organizations concerned in medical research. The Burma Medical Research Institute is an executive arm of the Burma Medical Research Council and was opened in June 1963. The pattern on which the Council and the Institute have been founded and are run is based on that of the Medical Research Council here and its associated institute at Mill Hill. There are at present departments of bacteriology, experimental medicine, haematology, instrumentation, medical statistics, pharmacology, and physiology. The work on which they are at present engaged appears to have been well chosen, with the object of providing a baseline from which future studies can be extended. They are concerned with such subjects as prevalence of anaemia in Burma, the various blood groups in the country, the occurrence of haemoglobinopathies, biochemical norms in Burma, normal pulmonary capacity of Burmese, the pathology of liver disease in Burma, and the thiamine content of various strains of rice—important because there is still a great deal of beriberi in Burma.

School of Preventive and Tropical Medicine, Rangoon

Great efforts are being made to take curative and preventive medicine to the people, particularly those in the rural areas where 85% of Burma's population live. With the object of providing well-trained staff in sufficient numbers for carrying out this programme a School of Preventive and Tropical Medicine has been established and at present is being housed in No. 1 Medical Institute, Rangoon. Emphasis is of course to be entirely on diseases endemic in Burma ; the course will cover clinical and preventive aspects of these diseases and will occupy one academic year. The school was opened in the autumn of 1966 and 10 students were then to be admitted. The teaching departments comprise tropical medicine, hygiene and public health administration, epidemiology and statistics, and microbiology, with subsections for bacteriology, virology, parasitology, and serology. A comprehensive syllabus has been drawn up which should well equip those who are to go out into the districts as township medical officers with their teams and take part in the scheme of medical care outlined in the earlier part of this paper.

There are many doctors in Rangoon who are old students of schools in this country, and it is planned to continue to send as many as they have foreign exchange for or scholarships for, particularly to our more advanced diploma courses. One of the delights of going to Rangoon was to be greeted by 15 of my old D.T.M.&H. students, who arranged a very enjoyable reunion dinner.

Conclusion

Burma is an exciting place to be in ; the Burmese are working very hard with comparatively little and they are doing important things in a very workmanlike way. The recent recognition by the General Medical Council, London, of the Burmese medical degrees is further evidence of this. The Burmese are keen to have constructive criticism, and throughout my visit it was emphasized that they wanted that, not praise. Behind all this activity is their Prime Minister, General Ne Win, with his solid practical approach.

I came away with very great admiration for the approach to medical problems which is being followed in Burma, and I am sure that there are opportunities for co-operation between our two countries in this field. We can probably help them with selected personnel, and an epidemiologist for the new school of preventive and tropical medicine has already been seconded from the Department of Clinical Tropical Medicine, London School of Hygiene and Tropical Medicine. The fund of good will towards British people in Burma is immense. If their material resources could match their good will the Burmese would indeed be ideally placed.

There is much to be learnt from the way many things are being tackled in Burma and especially in the medical sphere, where dealing with large problems of disease is being imaginatively undertaken with limited resources. The Burmese have much to be congratulated upon. We for our part can help in various ways in this venture, and it is here, in increasing co-operation between the two countries, that this article may perhaps bear results.

Approved Names

The second supplement to the November 1966 consolidated list of Approved Names is printed below. Communications relating to Approved Names should be addressed to the Secretary, British Pharmacopoeia Commission, General Medical Council, 44 Hallam Street, London W.1.

Approved Name	Other Names	Action and Use
Alprenolol	1-(2-Allylphenoxy)-3-isopropylaminopropan-2-ol Aptine is the hydrochloride	Beta adrenergic receptor blocking agent
Amfonelic Acid	7-Benzyl-1-ethyl-4-oxo-1,8-naphthyridine-3-carboxylic acid	Central nervous system stimulant
Aprotinin	Trasylol	A polypeptide proteinase inhibitor
Clorazepic Acid	7-Chloro-2,3-dihydro-2,2-dihydroxy-5-phenyl-1*H*-1,4-benzodiazepine-3-carboxylic acid AH 3232 is the dipotassium salt	Sedative
Diacetamate	4-Acetamidophenyl acetate	Analgesic
Droperidol	1-{1-[3-(4-Fluorobenzoyl)propyl]-1,2,3,6-tetrahydro-4-pyridyl}-benzimidazolone Droleptan	Neuroleptic
Felypressin	2-Phenylalanine-8-lysinevasopressin Octapressin	Vasoconstrictor
Gestronol	17-Hydroxy-19-norpregn-4-ene-3,20-dione Gestonorone (I.N.N.) SH 582 is the hexanoate	Progestational agent
Lidoflazine	*N*-{4-[4,4-Di-(4-fluorophenyl)butyl]-piperazin-1-ylacetyl}-2,6-xylidine	Cardiac stimulant
Mafenide	*α*-Aminotoluene-*p*-sulphonamide	Antibacterial agent
Meclofenamic Acid	*N*-(2,6-Dichloro-*m*-tolyl)anthranilic acid	Anti-inflammatory
Mepivacaine	1-Methyl-2-(2,6-xylylcarbamoyl)-piperidine Carbocaine	Local anaesthetic
Mithramycin	An antibiotic produced by *Streptomyces argillaceus* and *Streptomyces tanashiensis*	Antibiotic
Pancuronium Bromide	2*β*,16*β*-Dipiperidino-5*α*-androstane-3*α*,17*β*-diol diacetate dimethobromide	Neuromuscular blocking agent
Prazitone	5-Phenyl-5-(2-piperidyl)methylbarbituric acid AGN 511 is the hydrochloride	Antidepressant
Propyphenazone	4-Isopropylamino-2,3-dimethyl-1-phenyl-5-pyrazolone Present in Gevodin	Analgesic
Quinestrol	3-Cyclopentyloxy-19-nor-17*α*-pregna-1,3,5(10)-trien-20-yn-17-ol Estrovis	Oestrogen
Taloximine	4-(2-Dimethylaminoethoxy)-1,2-dihydro-1-hydroxyiminophthalazine	Respiratory stimulant

CONFERENCES AND MEETINGS

Otolaryngology Conference

[FROM A SPECIAL CORRESPONDENT]

The Second British Academic Conference in Otolaryngology took place in Oxford from 30 July to 4 August. It was attended by nearly 800 surgeons from 40 different countries.
